Locomotive Power

How Professor Dalby Calculates It

THE excellent address prepared by Prof Dalby as president of Section G, at the last meeting of the British Association, has not received the attention it deserved. The audience was scanty although the subject was attractive— British Railways Some Facts and a Few Problems. The address as a whole was not delivered; but Prof. Dalby talked about it, and received a vote of thanks There was no discussion although it presented many points for argument and careful consideration Its interest lies principally in the comparison drawn between railway working in the present day and in 1840 A dozen examples might be picked out in a few minutes. Thus for instance Prof Dalby tells us that the gross receipts of the London and North-Western Railway in 1908 were twenty two and a half times as much as those of the London and Birmingham Railway in 1840 and that the track mileage open was about twenty two times as great. The money earned per mile of track open is thus practically the same after a lapse of seventy years To earn the same amount per mile of track open however the trains of the London and North Western Railway had in 1908 to run 68 8 times the number of train miles that the trains of the London and Birmingham Railway ran in 1840 That is to say in order to earn a sovereign a London and North Western train has now to run three times the distance which it was necessary for a London and Birmingham train to run to earn the same amount.

The most interesting portion perhaps of the address concerns the power exerted by locomotive engines in hauling fast trains Here Prof Dalby entered on highly debatable ground He calculates the power in terms of tons of total load including engine and tender speed and train resistance He takes the Scotch express—Euston to Edinburgh—and he reduces his calculations to the form of a diagram Typical trains he tells us weighed in 1864 1885 and 1903 respectively 100 tons 250 tons and 4 0 tons The average speed in 1864 was 40 miles per hour in 1885 45 miles and in 1903 about 52 miles per hour The engine powers were 100 400 and 1 000 horse Precisely what the word power means we are not certain but we gather that it is not the indicated power but that obtained by multiplying the weight by the resistance and the velocity in feet per minute divided by 33 000 which gives a result less than the indicated power by the amount required to overcome the internal friction of the machinery We do not think that the load was ever so small as 100 tons in 1864 The work was largely done by the 'Problem or Lady of the Lake class with outside cylinders and 7 foot 6-inch wheels. These engines weighed full about 30 tons and the tender 18 tons or say 48 tons which left a very small proportion for the train proper if the total was only 100 tons During the race to the north in 1888 the train consisted of four coaches weighing 80 tons But while we believe that Prof Dalby underestimated the power required in 1864 we are equally certain that he overestimates it for 1903 No locomotive has yet been made for working express trains in this country which will continuously exert 1 000 horse-power between Euston and Edinburgh or Euston and Carlisle It must not be forgotten that the power as stated by Prof Dalby is that required to maintain speed on a level He bases his calculations on the formula $T = 5\,1/3 + \frac{V^2}{256}$ where T is the tractive effort. Thence he deduces that horse-power developed at the driving wheels is—

$$H\ P = W\left(\frac{V}{70} + \frac{V^3}{96\,000}\right)$$

We do not know where Prof Dalby got his resistance formula There are of course a great number from which to select but that which he has chosen is much too high Sinclair deduced from tests made on the New York Central and Hudson River Railroad

$R = 2 + \frac{V}{4}$ The Baldwin Locomotive Works use

$R = 3 + \frac{V}{6}$ M Laboriette s French experiments gave

$R = 3\ 2[illegible] + \frac{V^2}{281}$ Mr Deeley on the Midland arrived

at $R = 3 + \frac{V^2}{290}$ If we take Laboriette we get for [illegible]2 miles an hour 12 3 pounds per ton and for Deeley 11 8 pounds Let us take the round number 12 pounds and we have for 4 0 tons a gross steady tractive effort on the level of [illegible] 400 pounds Now [illegible]2 miles an hour is 4[illegible]76 feet per minute and $\frac{4[illegible]6 \times [illegible]400}{33\,000} = 749$ H P or 75 per cent of the power stated by Prof Dalby—a not unimportant difference It is well to remember that in the conduct of railway traffic it is the last straw that breaks the camel s back While a big engine may develop 700 horse power with ease and economy to get 1 000 out of it may involve much waste and wear and tear and the extreme probability that the driver and fireman having nothing in hand will fail to keep time with punctuality

Prof Dalby asks the very pertinent question What is the maximum power that can be obtained from a locomotive within the limits of the construction gage on British railways? This of course refers to engines of norm[illegible] [illegible]ster double engines [illegible] [illegible]uth America by the [illegible] [illegible] Newton le Willow[illegible] [illegible]ing the question [illegible] [illegible] a large number of [illegible] [illegible] that if the indicated horse-power be plotted against the rate at which heat energy is transferred across the boiler heating surface the points fall within a straight line region providing that the regulator is always full open and that the power is regulated by means of the reversing lever He has prepared a diagram setting this out graphically The diagram indicates that the indicated horse-power is practically proportional to the rate at which heat is transferred across the boiler heating surface and as this is again proportional to the extent of the heating surface, the limit of economical power is reached when the dimensions of the boiler have reached the limits of the construction gage the boiler being provided with a fire grate of such size that at maximum rate of working the rate of combustion falls between 70 pounds and 100 pounds of coal per square foot of grate per hour A boiler of large heating surface may be made with a small grate necessitating a high rate of combustion to obtain the required rate of heat production Then although a large power may be obtained it will not be obtained economically

316883
IARI

We confess that this proposition puzzles us Ostensibly it quite ignores the way in which the steam is used The units transmitted produce the same quantity of steam per unit no matter at what rate the transfer proceeds and the weight of steam is the measure of the power of the locomotive no matter in what way it is used But it seems to be obvious that if an engine is taking steam for 80 per cent of its stroke it will require a greater weight per horse-power per hour than it will if the valve gear is cutting off at 60 per cent which is of course contrary to Prof Dalby If he is right then an invariable relation exists in every locomotive other things being equal between the quantity of coal put into the fire-box and the horse power of the engine Indeed he expressly states that waste is represented by sparks ejected from the chimney and that the change in efficiency is small notwithstanding large changes in the indicated horse power Our readers will we feel sure agree with us that this is a very remarkable proposition as it stands It certainly comes as a discovery for so far as we are aware no one has ever hinted at the existence of an invariable relation between the quantity of coal put into a boiler furnace and the power got out of the steam resulting from its combustion It has of course long been known that the power depends on the quantity of coal burned Some years ago Mr Wolff in his book Modern Locomotive Practice put this very tersely by saying that at high speeds the maximum horse power a locomotive can exert is practically a constant being determined by the amount of water the boiler can evaporate If this were what Prof Dalby means then he would not have claimed to have made a discovery Perhaps Prof Dalby will favor us and our readers with a correction quite necessary if we have failed to understand him

It is worth while to give a few figures showing what must take place in a locomotive working up 1 000 indicated horse power The weight of steam required will be about 25 pounds per horse per hour or a total of 25 000 pounds To evaporate this would demand at least 3 500 pounds of coal The grate area is about 22 square feet in the engines of which Prof Dalby speaks Therefore to burn 3 500 pounds of coal per hour nearly 160 pounds must be burned in the same time per square foot which at 52 miles an hour means a consumption of about 70 pounds of coal per train mile Nothing approaching these figures obtains continuously on any English railway That a big modern engine can be made to indicate considerably over 1 000 horse power for short spurts is quite well known but this is a very different thing from a continuous effort such as Prof Dalby appears to have had in mind —The Engineer

The Effect of Silver Bismuth and Aluminium on the Mechanical Properties of "Tough-Pitch Copper Containing Arsenic

BEFORE the Institute of Metals Mr F Johnson stated that he melted electrolytic copper in a crucible and added the desired quantity of arsenic in the form of an alloy of arsenic and copper then the pure metallic silver bismuth or arsenic was added the metal well stirred and samples poured from time to time till the flat surface of the solidified ingot showed that the metal was at tough pitch An ingot 6½ by 1¼ by 1¼ inches was then cast in an open chill mold, reheated to a bright red heat and rolled to a rod 4 feet long by ½ inch diameter From these rods pieces were cut for the mechanical tests (bending, alternating stress malleability and tensile [illegible]) and for chemical analysis The chief results [illegible] follows All the 'tough-pitch samples contain[illegible] arsenic (0.26 to 0 52 per cent) show improved [illegible]chanical properties over the "tough pitch pure [illegible] similarly treated. The presence of arsenic [illegible] the percentage of oxygen needed to bring the [illegible] to "tough-pitch." After hot-rolling, quench[illegible] [illegible] greater toughness on the bars than slow [illegible] [illegible] up to 0.1[illegible]5 per cent in presence of [illegible] [illegible] the hot-working properties [illegible] [illegible] and raises the elastic limit It does not seem to influence the tough pitch stage Bismuth is detrimental even in presence of arsenic but as much as 0 05 per cent with 0 3 to 0 4 per cent of arsenic is not ruinous Hot working improves the metal containing bismuth for further mechanical treatment The effect of bismuth is to raise the tensile strength and extensibility but to lower the elastic limit and resistance to alternating stress It causes more oxygen to be required to reach tough pitch 'Tough pitch pure copper with 0 02 per cent of bismuth is much worse mechanically than tough pitch arsenical copper with 0 05 per cent Aluminium added to tough pitch arsenical copper so as nearly to deoxidize it (0 014 per cent) does not affect its hot working properties but lowers its tensile strength while increasing its toughness and ductility Excess of aluminium however (0 3 to 0 4 per cent) is disastrous to the hot-working properties of the metal and impairs its mechanical properties in the rolled condition Microscopic examination shows that bismuth separates out from copper containing it, on solidification in elongated plates or crystals which separate the crystals of copper from one another Excess of oxygen appears to cause the bismuth to separate either as metallic globules or as irregular masses of a bismuth oxide, which have not the same effect in weakening the structure as the long streaks of bismuth in copper containing no oxygen.

In an address in geography before the British Association for the Advancement of Science Prof A J Herbertson in the Geographical Section reviewed the progress of the science and in the course of his remarks urged the need of establishing a government Hydrographical Department The absence of such a department would be recognized as serious if they considered how their water supply was limited and how much of it was not used to the best advantage He also argued that the information which many government departments were accumulating would become much more valuable if it were discussed geographically and if statistics were mapped and not merely set out in columns of figures Many Blue-books would be made interesting and more widely used if their facts were properly mapped

---

Some of the plants of the family *Cruciferæ* which grow in pastures are distinctly poisonous Among these dangerous plants are various species of mustard The field mustard or charlock which is very common in many parts of France is particularly dangerous The black mustard appears to be less irritant but it is not free from poisonous qualities Its seeds seriously affect the health of cows and make their milk unwholesome The white mustard is still less poisonous, but not entirely innocent

Modern Governing Mechanisms

A Review of American and European Devices

By Warren H Miller

Of the various governing systems used by European and American builders of gas engines and means for varying the explosion pressure and consequently the mean effective pressure may be classified as follows

1 Constant volume of charge and variable ratio of gas to air

2 Constant ratio of gas to air and variable volume of charge

3 Variable ratio of gas to air and variable volume of charge

For small engines means for simply varying the stroke of the inlet valve will answer for regulation by varying the quantity of a constant ratio mixture and this is used in the original Deutz gears illustrated in Fig 1 The governor alters the position of the fulcrum of the inlet valve lever *I* and thereby changes the stroke of the inlet valve In large engines however it is usually not practical to depend on the stroke of the inlet valve alone to determine the quantity of mixture admitted without imposing too much work on the governor and robbing it of its sensitiveness or else incurring the liability of the valve to reopen under the suction when only light charges are to be admitted For this reason nearly all the large governor mechanisms include a mixing valve through which the governor controls the mixture in addition to the main inlet valve for admitting the charge to the cylinder and keeping it there Fig 2 illustrates the Deutz mechanism used on large engines the engraving being made from a drawing of the 2 000 horsepower size The governing is by throttling and the volume admitted is controlled as in the small engine by means of the movable fulcrum shifting the fulcrum *f* alters the stroke of a pair of balanced gas and air valves and the fulcrum at the left of the air valve spindle is also shifted still farther altering the opening of the gas valve The ratio of gas and air can be altered to suit the quality of gas by turning a handwheel which moves a sliding cage on the inlet valve stem

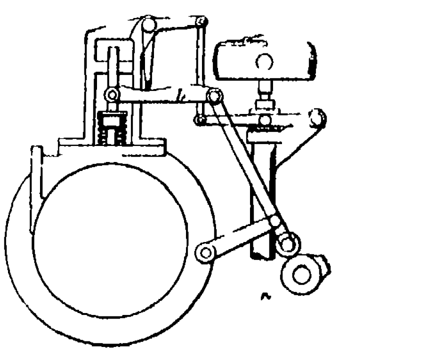

Fig 1 —ORIGINAL DEUTZ MOVABLE FULCRUM GEAR

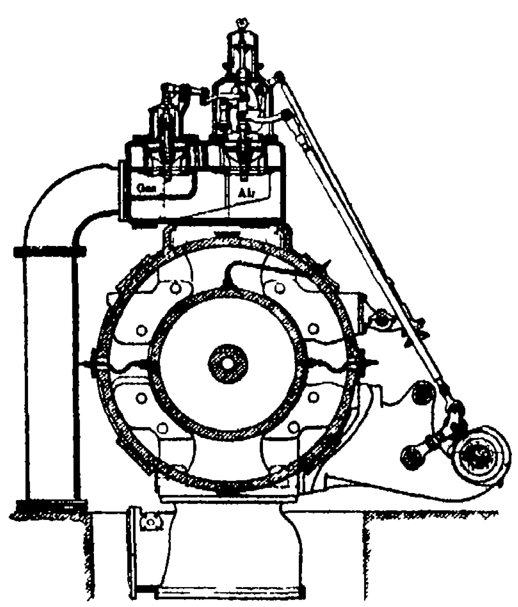

Fig 2 —DEUTZ VALVE GEAR FOR LARGE ENGINES

Fig 3 shows the form of shifting fulcrum gear devised by the Nürnberg company for varying the opening of the inlet valve The governor shifts the roller *R* and thereby varies the leverage of both the rocker arm *A* and the valve lever *L*

Fig 4 illustrates the cut-off governor gear of the Société Alsacienne It is somewhat similar to some of the American mechanisms in that it embodies a ported-cage mixing valve The inlet valve has a constant lift. The mixing valve shown in section in Fig 5 is a sliding cylinder with ports registering with ports in the housing which open into the gas and air mains It is divided circumferentially into air and gas ports in the correct ratio for the quality of gas used This valve remains normally down shutting the ports as shown in Fig 4 With each stroke of the eccentric rod operating the inlet valve the valve is lifted until the ports register with those in the housing and latched in that position allowing gas and air to flow through to the cylinder until the valve is released by a trip gear under the control of the governor when the latch is tripped the valve drops shutting the ports

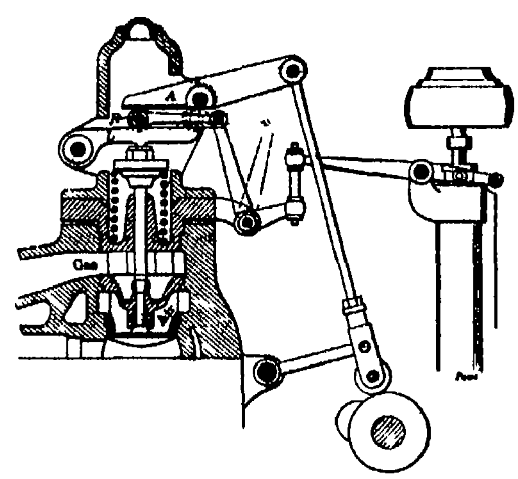

Fig 3 SCHMITZ MOVABLE FULCRUM GEAR

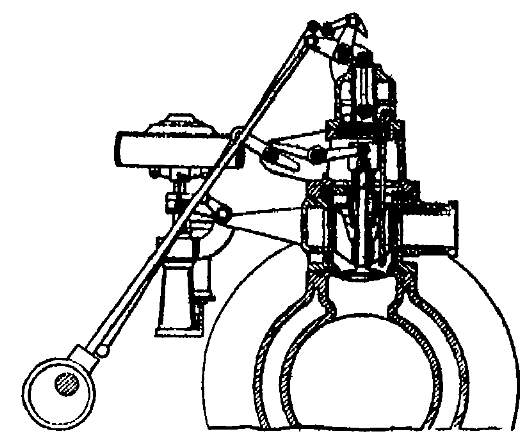

Fig 4 —ALSACIENNE VARIABLE CUTOFF GEAR

Fig 6 shows the mixing-valve gear used on the large size of the Nürnberg engine which is probably more familiar to American engineers than any other Continental engine Air is admitted throughout the suction stroke and the gas is admitted toward the end of the stroke both being shut off simultaneously at the end of the stroke The quantity of gas admitted is varied by opening the gas valve earlier or later in the stroke regulation is effected therefore by varying the quality of the mixture the volume being constant Fig 6 shows only the mechanism that operates the mixing-valve of which there is one on each cylinder placed midway between the two inlet valves which have constant lift and are opened by the usual cam rod lever combination A bifurcated arm *A* is pivoted at its fork ends to the outer housing and linked at the other end to one end of the bell crank *R* which is controlled by the governor The valve-operating lever *B* is pivoted at its inner end to the cylindrical member *C* which slides within another cylinder *E*, attached to the stem *S* of the valve, the lever *B* has a sort of rolling fulcrum on the arm *A*, and when the governor lowers the outer end of this arm, the "heel" of the lever *B* strikes the arm of the arm *A* later in the stroke and therefore opens the valve later and reduces the explosive mixture. The lever *B* opens the valve by lifting the sleeve *E* through the medium of a dog *D*, pivoted to the plunger *C* and this dog is tripped at the end of the suction stroke no matter at what point the valve is opened When the dog is tripped the valve is closed by the helical springs in the bonnet

The governor gear of the John Cockerill Company of Seraing Belgium also belongs to the variable-quality constant volume class but the mechanism is so designed that it can be used for either quantity or quality regulation Fig 7 shows longitudinal and transverse sections of the Cockerill engine cylinder and the principal features of the valve gear

The inlet valve has constant stroke and a sliding air valve moves with it so as to admit air synchronously with the opening of the inlet valve The gas valve is mounted above the air valve on a concentric sleeve and its actuating lever *L* is normally latched at the outer end by the dog *D* When the push rod *R* is forced upward by the inlet cam it opens the inlet valve and at the same time compresses a spring in the housing *S* which is attached to the lever *L* This would open the gas valve but for the latch *D* and this latch is tripped by the governor sooner or later in the stroke allowing the spring at *S* to open the valve The valve is closed at the end of the stroke by the downward motion of the housing *S* due to the fall of the push rod *R* when released by the main cam

The tripping rod *T* is moved back and forth by a small eccentric on the main shaft and its engagement with the dog *D* is timed by the governor through a mechanism which shifts the pivot of the intermediate rocker arm.

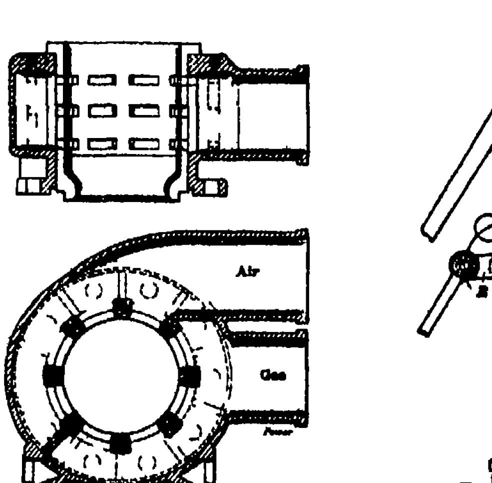

Fig 5 —ALSACIENNE MIXING VALVE

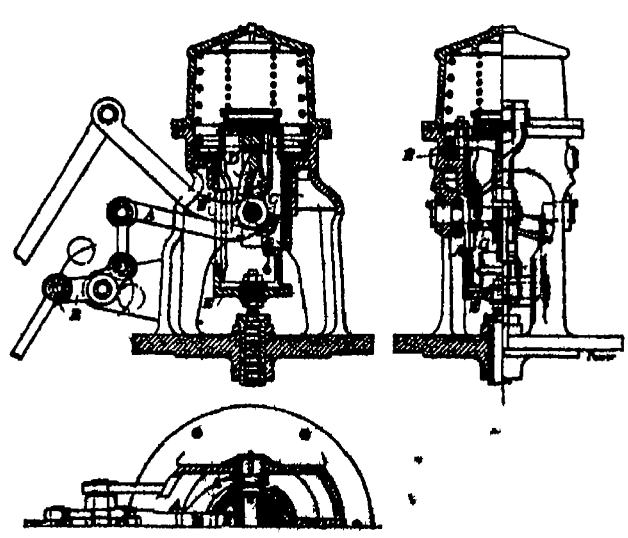

Fig 6 —NÜRNBERG VARIABLE CUTOFF GEAR

By extending the hollow spindle of the gas valve downward unpinning the air valve from the inlet valve stem and attaching it to the gas-valve spindle, the gear can be changed to quantity regulation.

A very [illegible] English gear operating on the variable-quality constant-volume plan is that of [illegible] shown in Fig. [illegible] [illegible]

* Power and the Engineer

lever system opens the inlet valve against a spring. The nut *M* on the inlet-valve stem tends to carry the gas-valve down with the inlet valve by compressing the spring *K*. The gas-valve disk *G* carries an upward cylindrical extension *H* which terminates in a vacuum piston *P* and incloses the spring *K*. A protected opening *O* allows air to pass in and out of the space below the piston *P* and a check valve *N* prevents the entrance of air above the piston but allows the escape of any that may be there. A bleeder valve *J* controlled by the governor allows more or less air to enter the vacuum cylinder and vary the upward pull of the piston *P*. When the spring *K* is compressed by the downward movement of the inlet valve, it presses the gas valve open more or less according to the amount of air admitted by the valve *J* and the resulting degree of vacuum that a given downward movement of the piston *P* can form above it.

As all of the American gears excepting that of the Bethlehem Steel Company's engine have been fully described in Power there is no need to discuss any but the Bethlehem gear in this article. Fig 9 is a sectional elevation of the mixing valve cage and shows also the inlet and mixing valves and the immediate operating mechanism. In this gear the ported cylinder attached to the inlet-valve stem which was first used in this country on the Westinghouse engine has been applied but the ports are cut diagonally. This makes it possible for the governor to control both the area of the port openings and the length of time that they are open without using trips or cutoffs. The sleeve *S* is twisted about the vertical axis by the governor rod and the relative angular positions of the same amounts of gas and air. When the load lightens, the governor shifts the sleeve *S* around so that at each stroke the ports in the sleeve and those in the plunger overlap less and less until at very light loads they register only during the latter part

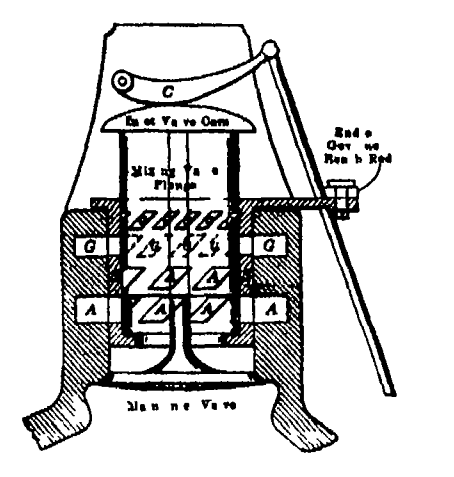

FIG 9 BETHLEHEM MIXING AND INLET VALVE AND CAGE

of the stroke. As the ports are very wide and slant at a considerable angle the governor has a very long selective range the total movement in an 800-horse power engine being about 3 inches on the surface of

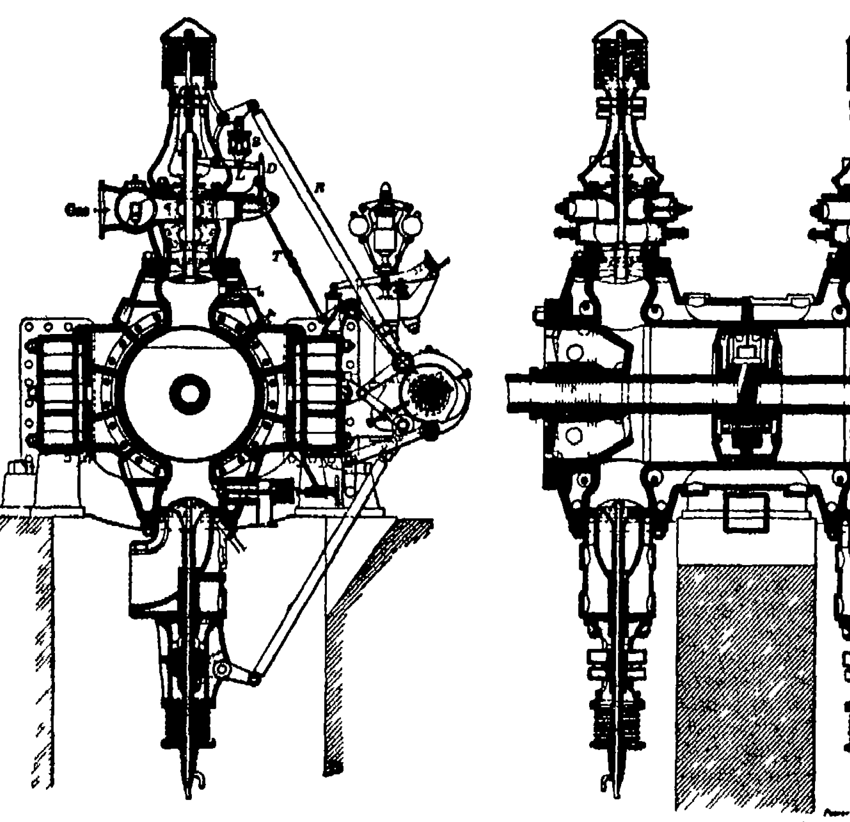

FIG 7—VALVE MECHANISM OF THE COCKERILL ENGINE

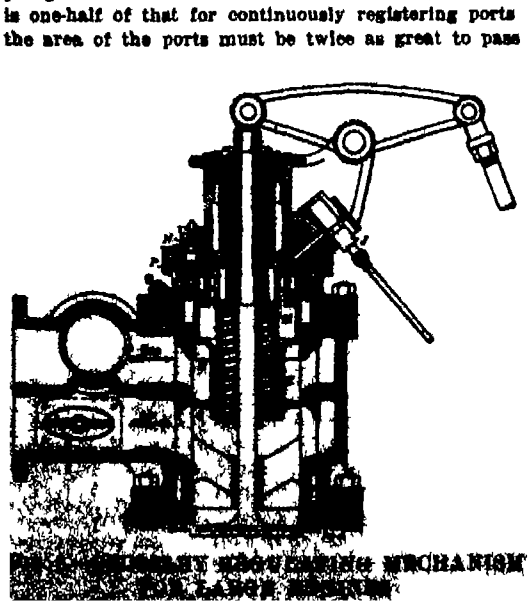
its ports and those in the mixing valve plunger are thereby varied. The mixing valve plunger is attached to the upper end of the inlet-valve stem and moves up and down with invariable stroke under the pressure of the cam *C* and the usual seating spring, which is not shown here. At full load the ports in the housing sleeve register completely with those in the plunger and since the total time that they connect is one-half of that for continuously registering ports the area of the ports must be twice as great to pass the sleeve and 7 inches at the pin on the outer end of the arm.

This gear is the latest one that has been developed in American practice and both this and the Westinghouse gears constitute an advance over English gears up to the present time in that they provide a variable cutoff without the use of any complicated trip arrangements or multiplicity of levers links cams etc.



GOVERNING MECHANISM ... LARGE ENGINE

The Sterilization of Milk

By Dr M Seiffert

The unsanitary and economically defective method of transporting milk in cans and pouring it repeatedly before it reaches the vessel of the consumer is still in general use. In this way the milk is exposed to contamination of many kinds and the visible impurities which it collects are not the least dangerous ones. The employment of cans for the transportation and sale of milk is also open to the objection that even when no fraud is intentionally practised by the dealer one customer may receive milk which contains much more than the normal proportion of cream, while another receives what is virtually skim milk. Unfortunately however the bottles and the method of sealing them which are now in use possess serious defects. The so-called patent bottles which are closed by a porcelain stopper and a rubber ring are condemned by the bacteriologist because they cannot be cleaned and freed of bacteria so perfectly as to make them fit containers for a liquid so prone to decomposition as milk. The bottles covered with paper caps are objectionable because the caps and the mouths of the bottles are handled in transport and therefore necessarily become conveyors of germs. Furthermore it is not practicable to make or to apply the caps by absolutely aseptic processes.

The new "uviol" method of bottling milk uses a seal which satisfies every requirement of bacteriological science and allows a perfectly aseptic handling of the milk. This seal is a disk of tinfoil which is coated on its lower side with a germ free stiffening material and which comes to the bottling room in a germ free package. The bottles are sterilized before being filled and are sealed by an automatic machine neither the seal nor the mouth of the bottle coming into contact with a human hand during the operation.

Another obstacle to the increased use of milk in large cities is the uncertainty whether the milk comes from healthy or from diseased cows. The old remedy for this state of things consisted in boiling the milk and thereby seriously impairing both its flavor and its nutritive value. The necessity of boiling all milk in order to escape the danger of swallowing disease germs has caused a great many persons to abstain from milk altogether. Those persons who prefer bottled milk in its natural condition to boiled milk are certainly far more numerous than those to whom the taste of boiled milk is not disagreeable. It is equally certain that raw milk is more effective than boiled milk in promoting the growth and increasing the blood supply of infants whose food consists entirely of milk.

In the manufacture of butter and cheese also sterilization of the milk by some method other than boiling is not only desirable but sometimes absolutely necessary. Although many butter makers pasteurize the milk it is well known that the process injures the flavor and quality of the butter. The heating of milk used for cheese making although it is enjoined by the new (German) cattle plague law cannot always be employed because it seriously affects the formation of the curd.

In the feeding of calves and pigs also experience has proved that better results are obtained from raw than from boiled milk and the feeding value of such waste products as curds and whey would be greatly increased if they could be used in the raw state without danger of infection with tuberculosis or intestinal disease.

For these reasons the uviol process which destroys disease germs but spares the acidifying organisms in milk has been developed. The process is based upon the power of violet and ultra violet rays to paralyse the growth of vegetable organisms. The bactericidal efficiency of these rays is now universally recognized. By the uviol process the germs of disease chiefly tubercle bacilli and pus forming bacteria which the milk of a cow may contain even before the veterinary inspector can detect the disease and remove the animal from the herd are killed without altering the natural state of the raw milk.

In the industries dependent on fermentation also the uviol process will soon find important applications as yeast and mold fungi are likewise destroyed though less rapidly than bacteria by ultra violet rays.

The success which has been attained in purifying water with ozone has naturally led to attempts to sterilize milk by means of the same agent. The experiments soon proved however that the conditions in the two cases are entirely different. In water the destruction of organic matter is desirable but in milk this must be avoided if the milk is to remain fit for use as food. The quantities both of organic matter and of bacteria which the two liquids contain also differ widely. Even the results obtained in ozoning water however appear to indicate that milk cannot be perfectly sterilized by direct action of an electric current because the ozone generated by the current passes through the liquid in large bubbles making unfit for use those portions of the milk which it touches and exerting no germicidal action on the rest of the milk. In order to sterilize milk completely without injuring it the ozone must pass rapidly through it and come into contact with every particle.

For this purpose Dr Emil Wiener has made experiments with atomizers producing sprays of exceeding fineness in which the diameters of the drops range from 12 to 20 millionths of an inch. As these drops are little larger than bacteria any bacteria which they contain are fully exposed to the action of ozone coming into contact with the drops and are instantly killed even by greatly diluted ozone. The ozone is then quickly removed from the milk by the same apparatus by which it is applied. In this apparatus the milk is atomized by a jet of compressed air mixed with ozone. The milk falls to the bottom of a glass vessel from which the ozonized air escapes by an orifice above the level of the liquid. Before the milk is drawn off it is thoroughly aerated by a current of compressed air which has been filtered through glass wool calcium chloride and soda lime. In this way Dr Wiener succeeded in freeing milk completely from disease germs and toxins and improving its "keeping" qualities without affecting its taste odor or chemical composition.—Umschau.

Progress in Aviation in 1910

A Review of a Remarkable Year

By Rene Gasnier

At the end of each year it is interesting to review the progress accomplished and the tendencies developed in aviation

The most striking feature of aviation in 1910 is the number of remarkable exploits performed during its last few months Nothing seems impossible to aviators The offer of a prize of $20 000 immediately brings out new men who accomplish often with loss of life feats that yesterday seemed impossible Most of the numerous fatalities are due to the breaking of parts during flight Casualties caused by landing and by capsizing in squalls are comparatively infrequent Hence aeroplanes should be constructed with the factor of safety employed in other constructions and as the breaking of a part is generally irreparable all important parts should be duplicated Several aeroplanes with double running rigging and rudder controls have been exhibited The Maurice Farman is especially well made in this respect and all moving wires run on ball bearing pullies

The types which we had to review last year were the Voisin Farman Wright and Curtiss biplanes and the Antoinette one seated Blériot two seated Blériot and Santos Dumont monoplanes We will examine the changes made in these machines this year and briefly mention the newcomers

Last year the Voisin obtained lateral stability from vertical partitions which gave it the appearance of a cellular kite This unsatisfactory device has been replaced by ailerons resembling those of the Farman Lateral equilibrium can apparently be maintained equally well by employing ailerons or by warping the sustaining planes although warping is evidently a more powerful means especially in monoplanes where it is the only method in use In biplanes warping slightly weakens the transverse frame In very large biplanes ailerons would probably be used exclusively

Last year the Wright had an elevating rudder in front but none behind and was consequently very unstable Its stability has been very greatly improved by adding a horizontal rudder behind which works in combination with the forward rudder This result suggested to constructors the possibility of suppressing the forward rudder altogether This was done in the case of the Voisin biplane which subsequently made the remarkable flight from Paris to Bordeaux Wright and Farman have also obtained excellent results from the suppression of the forward rudder For the present however Farman together with Maurice Farman and Sommer retains the combined forward and after rudders

The possibility of flying with a single horizontal rudder placed at the stern shows that the true type is that of the French school the monoplane constructed on the model of a bird As I predicted last year this form has triumphed over the American type having a forward rudder which tends to destroy the equilibrium

This year two new biplanes have appeared the Bréguet and the Goupy which resembles monoplanes in the relative positions of the sustaining planes, motor rudder and pilot This is the true type of aeroplane whether monoplane or biplane The biplane construction allows the sustaining surface and consequently the load to be increased almost indefinitely The monoplane opposes less resistance to forward motion and can therefore attain greater speed with equal power It also maintains its equilibrium better in high winds owing to its greater velocity and its greater weight in proportion to surface and because its single plane is less affected by gusts and eddies than the superposed surfaces of the biplane

Whatever the type of aeroplane the aviator is far better protected from injury in the event of a bad landing if his seat is behind the motor than if he sits in front exposed to the first shock and liable to be hit in the back by the motor

The monoplanes have changed little during the year The Antoinette remains exactly as it was and the one-seated Blériot has undergone very slight modifications The Blériot with two seats beneath the wings has given place to a form in which pilot and passenger sit side by side in the position occupied by the pilot of the smaller machine The Santos-Dumont remains unchanged This machine is far safer than is generally believed and it would work well if a sufficiently light low power motor could be obtained

Among the new monoplanes the Hanriot, which resembles the Antoinette has performed very well in the contests in which it has taken part. The Tellier is a modified Blériot, with especially well-constructed rigging The Nieuport is a machine of peculiar type which opposes very small resistance to forward motion The Sommer closely resembles the Blériot. The Esnault-Pelterie looks like a great bird and in a beauty contest I would award the highest prizes to this machine and the Antoinette

It is almost impossible to give complete and exact descriptions of the different types because their motors and the area and curvature of the planes are not the same in all machines of the same type One Blériot for example has a 25 horse-power motor a greatly curved sustaining surface of 172 square feet and a speed of 37 miles per hour another has a 50 horse-power motor a slightly curved surface of 150 square feet and a speed of 65 miles a third has a 100 horse power motor a perfectly flat surface of 129 square feet and a speed of 81 miles The form of the curvature varies greatly in the different types Antoinette always employs the arc of a circle but the wings of most other machines have a maximum curvature near the front and some have an inverse curvature close to the edge Some machines have flexible wings These diverse forms have been adopted after testing a few surfaces with the dynamometer We are still far from perfection and we have no very precise data to guide us to it All constructors except Henry Farman employ thick wings The center of gravity has scarcely shifted In monoplanes it lies almost immediately under the wings and relatively higher than in biplanes where it is situated from 12 to 16 inches above the lower plane The stabilizing planes contribute to support in the one-seated Blériot and the machines of both Farmans Voisin and Sommer but not in the two-seated Blériot the Antoinette Esnault Pelterie or Hanriot Which of these systems is the better? We see that Blériot employs both

In some machines the pilot is placed in front of the motor in others behind it The distance between these two principal weights varies from nothing in the Wright where the pilot sits beside the motor to 13 feet or more in the Antoinette which is the most sluggish in evolution of all aeroplanes Blériot seems to have found the happy mean which allows the bow to be raised quickly enough to land easily and safely

All aviators are now agreed in preferring the start from wheels which Wright the only one who did not employ it has at last been forced to adopt With the great and swift machines of the future skids and rails may again become necessary In landing, some aviators use wheels some skids and some employ both skids and wheels Blériot and Voisin rely entirely on wheels but this is a bad plan because the machine runs a long distance on the ground and may be upset by a stone or a hole A better system is that employed by Farman Sommer and Hanriot in which skids pushed down to the ground after striking take the load from the wheels and quickly bring the machine to a stop There is also a tendency to use retractile starting wheels and to land on the skids alone In my opinion this is the best method It has been proved that if the pilot has an unobstructed view in front he can land very gently without employing springs even with the heaviest machine In monoplanes the shock of landing is often increased by the fact that the pilot cannot determine the instant of striking with precision A skid flanked by two wheels is often used in monoplanes This excellent plan has been adopted by Esnault-Pelterie and Nieuport.

Systems of rudder control show as much diversity as they did last year I prefer Blériot's well known system which is also employed by Tellier The same effect is produced by the single lever of Farman and Sommer Several pilots have passed from Farman to Blériot machines and have at once guided the latter perfectly The same movements are required in both machines—forward for rising, backward for descending to right or left for warping the planes or inclining the ailerons—and in both the steering rudder is operated by the feet. The Blériot system, however with its little wheel directly in front of the pilot and turned with either hand, appears more practical.

Great improvements have been made in the construction of aeroplanes during the past year Some makers turn out machines in stock sizes, with all of their parts carefully finished. The Blériot and Esnault-Pelterie machines are particularly well made. A few aeroplane makers are beginning to construct frames entirely of steel tubes. Voisin [illegible] a machine built of tubes which are joined [illegible] tubes, in addition to their other merits, keep their shape when exposed to dampness, which rapidly warps wooden frames On the other hand steel deteriorates when subjected to vibration, and airship builders have encountered serious difficulties in the construction of long gondolas of steel tubing Hence I should prefer to retain wood as the main constructive material although steel tubes might advantageously be substituted for some of the vertical supports The Antoinette machines are always flawless in construction I am glad to see that several constructors are substituting steel ropes like those used in ships, for the piano wire which breaks so frequently

The wooden propeller has finally won the field This year the metal propeller is employed by Voisin alone The wooden propeller is more efficient than the metal propeller because it is perfectly smooth and it is also far safer Reducing gear is seldom used although it presents certain advantages Bréguet has carried five persons with a propeller geared to make 600 revolutions per minute The direct drive is preferred however because of its lightness and simplicity The diameter of the propeller which last year was generally about 7 feet has been increased to 8½ or 9 feet. A large propeller geared down to 600 revolutions would be desirable for a machine of great surface carrying several passengers but for a small and swift monoplane the propeller attached directly to the motor shaft is preferable Twin propellers are used in few machines except the Wright and the Lioré They present little advantage and increase the chance of accident Chauvière exhibited at the Salon d Aviation an interesting device for testing propellers on an automobile

Many pages might be devoted to motors Last year we had few light weight types but there are many this year At the head of the list stands the admirable Gnome motor with which many of the remarkable recent feats of aviation have been accomplished Many persons at first did not believe in the rotary motor but they have been compelled to accept the facts This admirably simple device represents the true type of aeroplane motor and a step toward the ideal turbine motor Many motors with four and eight cylinders are highly esteemed but none of them rivals the Gnome in lightness Among the air cooled motors the Esnault Pelterie is remarkable on account of the severe tests which it has passed successfully Still more notable is the splendid performance of the Antoinette water-cooled motor which accomplished 1,800 miles in one week at the Bordeaux meeting. This would be a pretty good record for an automobile The aeroplane motor is evidently becoming sharply differentiated from its elder brother the automobile, and is assuming a form especially adapted to its own work Aviators are beginning to demand in addition to the greatest attainable lightness a small consumption of fuel and a range of speed which is indispensable for landing It is dangerous to descend rapidly with the motor working at full speed but if the ignition is cut off and the descent made by soaring it is impossible to start the motor again if a forward impulse is needed on approaching the ground If the motor would be kept going at a very slow speed which could be increased at the critical moment, the descent could be made with perfect safety

Two very original and interesting aeroplanes were exhibited at the Salon by Fabre and Coanda. The Fabre machine is the only aeroplane that has ever risen from and alighted on water Its trussed frame appears very strong, but it would be better to conceal the trusses inside thick wings The Coanda aeroplane has a fantastic appearance The resistance to progression is reduced to a minimum. The form of the wings, which are made of wood, was adopted after numerous tests made on rapid railway trains, but the wings appear weak, as they have neither vertical nor horizontal braces This machine is to be driven by a turbine which the inventor expects to develop astonishing power

Inventors have not made much progress this year The Salon had little to show except slight improvements on the types of last year The audacity of the pilots however, stimulated by the offer of large prizes, has revealed unsuspected qualities in the aeroplanes. Let us hope that the invention of new types will be similarly encouraged next year. The [illegible] of the Salon [illegible] Blériot, [illegible] Voisin, the Wrights [illegible] [illegible]

[illegible] general tendency toward uniformity of type is [illegible]. The monoplane and the biplane are progressing along the same lines, although their goals are different.

The time has come to build touring aeroplanes which will not break in the air The pilot and the passengers should be comfortably installed in cars securely mounted inside the frame where they will be protected as completely as possibly against the violent shock which is always liable to occur in landing on bad ground.

A good method of quickly stopping the aeroplane after landing is required There is still room for much improvement in the forms of wings and propellers and in diminishing the resistance to progression It is also necessary to organize soaring contests and to offer large prizes for the smallest angle of ascent At present what is called a soaring descent is a swift motorless dash down a grade of nearly 45 degrees

These are a few of the important problems that await solution With the motors now available this year's astonishing feats of aviation can easily be surpassed In 1911 we may expect to see the long-distance races which marked the early years of the automobile repeated with aeroplanes —Translated for the SCIENTIFIC AMERICAN SUPPLEMENT from L Aerophile

The Limits of Our Chemical Knowledge

Some Modern Problems

By Dr William Eichholtz

THE last few years have enriched science and technology with discoveries and inventions of the most sensational character It is not surprising that a generation which has witnessed the discovery of Roentgen rays and radium and the development of wireless telegraphy airships and aeroplanes should become *blasé* and refuse to be greatly impressed by anything The brilliancy of the new discoveries casts into the shade the years of patient toil which preceded them and also the numberless problems that yet remain unsolved

We know to-day that there is no specific vital force which gives vitality to all living creatures We think we know that life is merely the sum of the biochemical processes which take place in the individual cells of the organism and that these processes are governed by the same laws that govern chemical reactions in the laboratory But the chemical processes of the body though similar to those which we have learned to control in the laboratory are exceedingly complex and we know very little of their details

Many persons are surprised when they are told that it is impossible in some cases to detect adulteration of food and can scarcely believe that science is still so impotent Most articles of food are natural products and consist mainly of the very complex organic substances When it is explained that we do not know the chemical structure of albumen the most important constituent of every animal and vegetable cell and that most of the substances which give foodstuffs their characteristic flavors and odors cannot even be chemically defined it may be understood why the chemist finds it very difficult and often impossible to distinguish pure from adulterated wine or genuine from artificial butter

The statement that we do not know the chemical structure of albumen does not mean that we are entirely ignorant of the composition of albumen We know that albumen contains certain chemical elements combined in certain proportions but this knowledge does not give a mental picture of the structure of the albumen molecule

Quantitative analysis suffices to explain the composition of most minerals and inorganic salts but the quantitative determination of the elements of an organic compound gives little knowledge of the chemical structure and character of that compound In view of the small number of elements—carbon oxygen hydrogen and nitrogen—which make up most of the countless and infinitely diverse organic compounds percentages mean nothing and arrangement or structure is everything In many instances two or more obviously different substances have precisely the same percentage composition For example formaldehyde the aqueous solution of which is well known under the name formalin is identical in percentage composition with grape sugar and some other carbohydrates

The chemical investigation of natural products is made more difficult by the almost invariable association of a number of similar and nearly related homologous compounds Butter for example contains a long series of fatty acids which shade into each other so gradually that the series can only be resolved into a number of groups which defy analysis into their individual members Fruit juices similarly contain series of organic acids

The systematic methods of inorganic analysis are therefore inapplicable to organic bodies and the reproach cast upon food analysis has very little justification for it is not and it never will be possible to determine the ingredients of animal and vegetable products by the rigid system and with the absolute certainty with which a skilled chemist can analyze the most complex of inorganic substances

In many cases the adulteration or falsification of food products can be detected only by means of some unimportant ingredient which happens to produce a striking reaction For example genuine honey contains microscopic grains of pollen If these are absent the genuineness of the honey may be doubted Unfortunately however the adulterators keep pace with the progress of science and mix artificial pollen grains with their artificial honey All margarine sold in Germany must according to law contain an admixture of oil of sesame which produces a brilliant color when the reagent furfurol is added Without this admixture of oil of sesame it would be very tedious and difficult to distinguish margarine from butter This can be done in some cases by determining the proportion of volatile fatty acids which are usually more abundant in butter than in margarine The quantity of these volatile acids in butter however varies with the season the stage of lactation and the breed of cows and it sometimes falls below the prescribed limit It is especially difficult to discover whether a specimen of butter is adulterated with margarine and if so to what extent and in many cases it would be quite impossible to detect such adulteration without the compulsory 'latent coloring of margarine with oil of sesame

The detection of adulteration and falsification in wine is still more difficult It is known that there are mixtures sold as wine which contain not a drop of grape juice and which yet defy detection by chemical analysis The chemist cannot even distinguish the coloring matter of red wine from that of huckleberries probably because the two are chemically identical

The consumer however cares nothing for chemical identity He wishes to know the source of his food but in this inquiry the chemist is restricted to limits fixed by nature In one instance these limits have recently been transcended but not by the chemist. The nice discrimination between varieties of albumen which chemistry is unable to make has been brilliantly accomplished by biological science

If an extract of horse flesh or the serum of horse blood is injected repeatedly during a considerable period into the circulation of a rabbit a substance called an antitoxin which precipitates the albumen of horses and that alone is formed in the blood of the rabbit Hence if the serum of the rabbit which has been thus treated is mixed with an extract made from suspected meat the presence of horse flesh in the meat will be indicated by the formation of a precipitate This method is already extensively employed for the detection of horse flesh in sausages An antitoxin which precipitates human albumen alone and which is useful for the detection of human blood in the investigation of crimes is prepared by a similar process

This biological reaction which is called Uhlenhuth's reaction from the name of its discoverer is distinguished from most chemical reactions by its delicacy and precision It can be applied with success to exceedingly small quantities of matter

Our chemical knowledge then is still very imperfect but it must not be forgotten that chemical problems are proposed by nature and are as numerous as the products and processes of nature Every natural product theoretically presents three problems its composition its utility and its artificial or synthetic production

Technical problems which are not of chemical nature are usually accompanied by their solutions on their first appearance

The necessity of traveling 60 miles an hour was not felt until long after the steam engine had been invented Such wants are rather suggested and slowly impressed upon conservative humanity by the existence of means of supplying them Hence technical inventions are thankfully received as unexpected gifts while chemical discoveries are regarded as long deferred payments of just dues There are exceptions however to both of these rules The problem of flight has occupied humanity for thousands of years and on the other hand synthetic chemistry has given us medicines dyestuffs and other substances which have become indispensable although they occur nowhere in nature but were created in the chemical laboratory —Ueber Land und Meer

How Birds Work Together

TURNSTONE is the name of a variety of shore-birds that are allied to the plovers and the sand pipers This name has been given to them because of their singular manner of feeding With their strong bills they turn over the small stones lying in the sand of the beaches to find the insects that may be sheltered underneath. If the stone prove too heavy for the bill, they push it over by applying the breast to the upper side Frequently a number of these birds will work together to turn over an object that is too heavy for one alone to move

Two little workers were once seen busily endeavoring to turn over a dead fish that was fully six times their size. They were boldly pushing at the fish with their bills and then with their breasts. Their endeavors were, however, in vain and the object remained immovable.

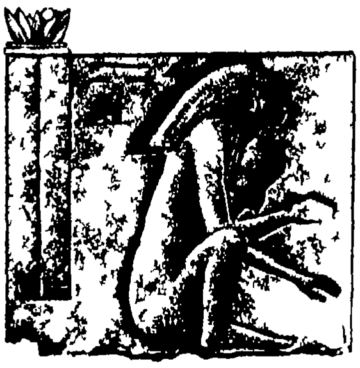
Then they both went round to the opposite side and began to scrape away the sand from beneath the fish. [illegible] removing a considerable quantity, they again [illegible] to the spot where they had been, and went [illegible] work with their bills and breasts, but [illegible] as before. Nothing [illegible] a second time to the other side and recommenced their trenching operations with a seeming determination not to be baffled in their object which evidently was to undermine the dead creature before them in order that it might be the more easily overturned

While they were thus employed and after they had labored in this manner at both sides alternately for nearly half an hour they were joined by another of their species which came flying with rapidity from the neighboring rocks Its timely arrival was hailed with evident signs of joy

Their mutual congratulations being over they all three set to work and after laboring vigorously for a few minutes in removing the sand they came round to the other side and putting their breasts to the fish succeeded in raising it some inches from the sand but were unable to turn it over It went down again into its sandy bed to their manifest disappointment.

Resting however for a space, and without leaving their respective positions which were a little apart the one from the other, they resolved it appeared, to give the work another trial. Lowering themselves, with their breasts close to the sand, they managed to push their bills underneath the fish, which they made to rise about the same height as before Afterward withdrawing their bills but without losing the advantage which they had gained they applied their breasts to the object This they did with such force and to such purpose that at last it went over and rolled several yards down a slight declivity It was followed to some distance by the birds themselves before they could recover their bearing

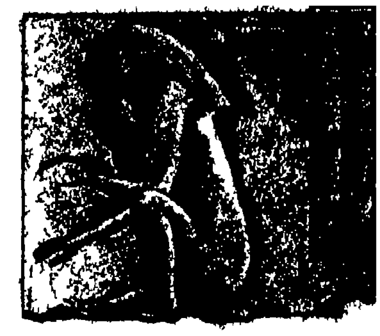
To Color Tin Solder Yellow —Prepare first a saturated solution of blue vitriol in water dip a polishing stick into it with which the place to be soldered is moistened Touch the spot thus moistened with an iron or steel wire or rod If this is frequently repeated copper will be deposited To produce yellow color the spot is moistened with a mixture of 1 part of saturated aqueous solution of white vitriol and 2 parts of blue vitriol solution by means of a zinc rod The spot is to be finally rubbed with gilding powder and polished with the burnisher In the case of gilded objects the coppered spot should be coated with a thin covering of gum or isinglass solution dusted with bronze powder and after drying brushed smooth For silver articles the coppered place is to be rubbed with silvering powder, brushed and polished.



The Temple of Hibis*

Results of the Metropolitan Museum's Expedition

By H E Winlock



During the past winter the Egyptian Expedition of the Museum has conducted the excavations at the Temple of Hibis in Kharga Oasis The temple is one built chiefly in the reign of Darius the Great about the beginning of the fifth century before Christ and its clearing was undertaken by the expedition because of its importance as the only architectural monument of the period between the decay of the Theban Kingdom and the conquest of Alexander the Great which exists today in good preservation

Prof Gaston Maspero Directeur Général du Service des Antiquités d'Egypte assigned M Emile Baraize an engineer of the service to the task of consolidating and restoring the temple at the expense of the Egyptian government while it was being cleared by the expedition The latter owes its acknowledgments to Prof Maspero for making it possible to conduct the two pieces of work—the clearing and the restoration of the temple—in co-operation and especially to M Baraize for his unfailing helpfulness not only in the special task he was undertaking on behalf of the service but also in all of the other work connected with the excavations The collating of previously published copies of the temple hieroglyphic inscriptions with the originals and the copying of inscriptions and scenes which have not been published heretofore or which have been brought to light during the past winter were started by N de G Davies of the expedition In connection with and supplementing the Davies copies Friedrich Koch has begun a series of photographs which it is hoped to finish during the coming season and which it is intended shall be a complete record of all the reliefs and inscriptions in the temple The Greek decrees mentioned in the expedition's last report as well as some new decrees shorter inscriptions and graffiti found this year have been copied and are being prepared for publication by H G Evelyn White while the plans and architectural gave up some of the land about the eastern gateways These questions took up a great deal of time throughout the winter and their ultimate solution was almost entirely due to M Baraize but meanwhile about the middle of December a preliminary agreement had been arrived at a light railway was installed similar to that which had been in use at Lisht, and excavations were begun at the portal of Darius and pushed westward From the very beginning of the excavations fallen blocks from the temple were found buried to greater or less depths in the soil and drift-sand First to be cleared was the portico of Nectanebo Part of the screen walls of the north and south sides had always remained visible above the surface but in the course of the excavations practically all of the columns and cornice which had risen above these two sides were brought to light lying just as they had fallen each stone in relation to the next in such a way that a reconstruction of the elevation could be definitely made As the work proceeded through the great eastern doorway of the temple the fallen blocks were found in greater and greater numbers until when inside the large hypostyle hall the removal of the sand brought to light a mass of stones in great confusion filling the hall to a depth of several meters above the pavement (Figs and 2) These were the drums and capitals of six fallen columns and the architraves and roofing slabs which had been supported by them Most of the columns could be completely recovered but the majority of the pieces from the roof were so broken that to restore them to their original positions was found to be impossible In order to continue the clearing all of them had to be removed but as the greater part were extremely massive the process was slow and difficult (Fig 1)

At this time the force of workmen numbered nearly two hundred and as it was impossible to employ so many in the hypostyle the majority were transferred trenches were sunk below the surface to bed rock On the west the work had to be stopped within ten meters of the temple wall; but on the south, where the cultivation did not approach the temple so closely a much larger area, covering about three thousand square meters was cleared (Fig. 3) The work at this point was extended early in February to a low mound rising on the edge of the cultivation where traces of buildings had been found on the surface. The greater part of the rest of the season was spent in exploring the network of mud brick walls uncovered here At the end of the work some modern structures were removed from among the eastern gateways but no other attempt to excavate in the palm grove has yet been made The work in the field was brought to a close the first of May

The consolidation and restoration of the temple by M Baraize was begun about the middle of January and continued to the end of the season A great deal of this time was spent in replacing with new masonry the stones in the lower courses which had been eaten away by the moisture and salts in the soil in which they had been buried In order to make the walls capable of sustaining their own weight after they were exposed In the case of one partly fallen column in the hypostyle hall this operation necessitated the taking down of the standing courses and the complete renewal of the foundations In addition a great deal of the fallen structure recovered in the clearing was restored to its original positions In the hypostyle two of the six fallen columns were set up again and some parts of the screen wall and columns of the offering hall a great many blocks of the fallen cornice from the exterior and some of the frieze at the top of the walls inside the temple were replaced and the greater part of the west wall of the temple was rebuilt from the bottom courses to its original height such of the blocks as

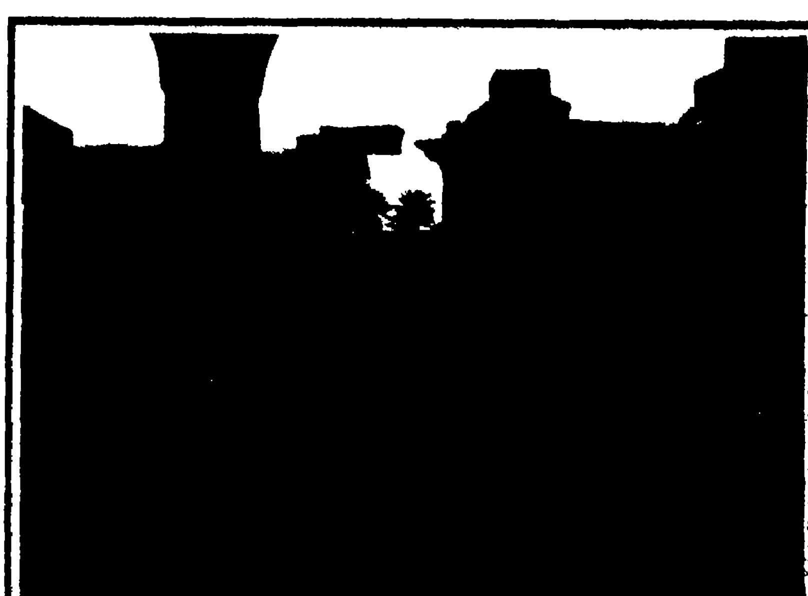


FIG 2 – HYPOSTYLE HALL LOOKING EAST AFTER THE REMOVAL OF THE SAND SHOWING FALLEN ROOF AND COLUMNS

FIG 1 – HYPOSTYLE HALL, TEMPLE OF HIBIS, KHARGA LOOKING WEST, DURING THE COURSE OF THE REMOVAL OF THE FALLEN BLOCKS

THE EGYPTIAN EXPEDITION

drawings are being done by William J Jones both of whom are members of the expedition

The field work in the oasis began the first of December As the temple is situated in the midst of the peasants farms the first step was to open negotiations with the land owners of the neighborhood with a view to procuring a place where the earth and sand from the excavations could be dumped and obtaining the title to some of the land in private possession adjoining the ruins which it was desirable to dig Eventually an arrangement was made by which the expedition was able to dump into a low salt marsh at the foot of the temple hill and in exchange for this filling and improvements of their lands, the owners to the excavation of the exterior Eventually as the entire task of transporting the blocks in the hypostyle was undertaken by M Baraize all of the expedition's workmen were engaged in running spurs of the light railway around the north and south sides of the temple and in clearing away the larger drifts of sand and débris collected there. In this way two side-openings were found into the offering hall, by which the chambers in the back of the temple could be entered and cleared while the hypostyle was still blocked The excavations on both sides of the temple were carried on by means of the railway down to the ancient surface level. To the north, an area of over one thousand square meters was dug in this way to a depth of two or three meters, and [illegible] were missing being replaced with new masonry. This restoration is to be continued next year in conjunction with the further excavation.

The clearing and rebuilding of the Temple of Hibis has disclosed new features in the plan and decoration, including some interesting reliefs which have been brought to light on walls heretofore buried. One shows the king, Darius, in a boat, picking [illegible] flowers to offer to the god Min, and another, the god Sutekh the popular deity of the oasis, [illegible] the Serpent of Evil (Fig. 4) In the ruins of the portico of Nectanebo there was found, [illegible] columns from the north and the [illegible] to be restored, as [illegible]

* Bulletin of the Metropolitan Museum of Art

its coloring almost intact. It is probably the capital of one of the four columns of the almost completely destroyed eastern façade, but although its position has been ascertained with a good deal of certainty not enough of the column and substructure remains to replace it. It has therefore been brought to the Metropolitan Museum of Art.

Additional knowledge of the history of the temple has been gained also by the excavations. A fragment was found of an offering bowl of dark blue schist way like those at Kom Ombo and Edfu has been discovered and dated to the reign of Ptolemy II Philadelphos (B. C. 285-247) from a fragment of the dedication inscription in Greek. Among the fallen blocks of this wall there have been found a great many pieces of relief of the reigns of Ptolemy III Euergetes (B. C. 247-222) and of a later Ptolemy and his consort Cleopatra, but it is impossible to tell yet whether they come from decoration of the wall itself or from some other structures which may have existed near by. Indeed the whole site seems to have flourished throughout the Ptolemaic period, as besides these structures and the inclosure wall and pylons on the east already known, there were discovered on the south the foundations of a large Ptolemaic brick structure with a stone portico and near by were found coins, pottery and small bronze ex-votos which had been originally in the temple. This prosperity continued at least to the first centuries of the Roman period, when a certain Herakleides dedicated a new pavement and one Heraklios built piers in the hypostyle to support the then endangered roof.

But from the third or fourth century after Christ evident signs of decay are noticeable. The inclosure walls were broken in places and private houses encroached on the temple area. From these the excavations recovered coins, ostraka, a bronze lamp and a good deal of pottery. At the abandonment of the temple as a place of pagan worship the dwellings were built against the outside walls and among the columns of the hypostyle halls and in the northeast corner there was erected a small Christian church. Fragments of glaze found in connection with this last occupation show that it continued until after the Arab conquest, archæological evidence which it is possible to verify inscriptionally by several Coptic graffiti in the tombs of the Necropolis el Haguat and on the rocks of Gebel-et Têr. Among these latter is a prayer signed and dated in the eighth century after Christ by Severus son of the Pagarch of Hibis.

What is the Ether?*

The History and Necessity of a Remarkable Conception

By Owen Ely

SINCE the time of Newton physicists have seen the n ed of assuming an ether to explain action at a distance or the passage of electric and magnetic forces through empty spa e Though these phenomena have been th r ugh y st died through experimental research comparat ve y little work has been done to deduce from the laws and facts at our disposal the real properties and onditions of the ether The concepts of a ether have generally been so mystical and vague that scientists have sh nned the task of correlating or confirming the n Bu more recently science has realized the importance of this realm of inquiry Lorentz Larmor Thomson Kelvin Lodge and others have sought some basis f experimentation and have attempted to b ild com lete and consistent theories Results are slowly a umulating more definite hypotheses are being formulated and perhaps a few more decades will give us a fairly complete knowledge of this understratum of nature

The first important theory of he ether was developed by Green and others in the early part of the nineteenth century The ether was regarded as a kind of incompressible jelly easily set a-quiver by the motions of the molecules and able to transmit this motion through its vast bulk to the ends of space And yet for any motions of matter other than the molecular the ether was thought to act as a perfect fluid This provision was ne essary to limit the ether to transverse vibrations Owing to the increasing demands which new dis overies in optics made upon the theory it was abandoned

One of the st pr ment theories which have been brought forward was that connected with Maxwell s electro magn ti theory of light The ether was ass med to be a bu ent fluid the particles of whi h osci late re olve or in some way change their on litio causi g the rapidly alternating polarizations whi h Maxw ll used to explain his conception of the ele tro-n ag etic wave Sir William Thomson in the Philosophi al Magazine for J ne 1853 gave the theoretical demonstration to prove that the reversing of an electric charge produces a polarization the same in kind as that which constitutes a light wave Later Hertz actually proved the identity But polarization is still little more than a name and there is yet some discussion as to whether it involves any bodily displacement of the ether

The ether having been regarded as a solid and a fluid it remained to treat it as a gas This was attempted by several among them Mendeleef the chemist But the results did not seem very satisfactory Evidently the ether needed properties of each state of matter solid fluid and gaseous Rigidity and elasticity of some sort were required that light should travel in a straight path the freedom of movement of a perfect fluid was necessary since apparently there was no friction between matter and ether and finally its inertness its fail re to affect matter of itself pointed to a la k of ohesion or activity among its partl les For those reasons apparently modern physicists have generally ceased trying to picture ether in terms of matter but rather are inclined to explain matter in terms of ether Thus Prof Osborne Reynolds who has worked upon his theory for many years regards the ether as a system of finely packed grains of which it would take same 112 10 to make 1 an inch and whose mean free path is 4 10 of their 1 amet r These round hard grains are piled up like billiard balls thro gh the universe but here and there is a cra k or separation and this vacuum is matter! The encounters of the cracks make up the phenomena of the cosmos

Larmor s concept seen s somewhat similar for he regards electrons as nuclei of permanent etherial strains in rapid motion Kelvin and his school lay emphasis upon an explanation of the ether s perfect elasticity Kelvin s famous theory of the ether makes its elasticity due to rotational motion—intimate fine-grained motion througho it the whole etherial region motion not of the nat re of locomotion but circula ion in closed c rves ret rning upon itself—vortex motion of a kind far more finely grained than any waves of light or any atomic or even electronic structure If the elasticity of any medium is to be ex plain d kinetically it follows as a necessary conseque e that the speed of this internal motion must be omparable to the speed of wave propagation that is say that the internal squirming circulation to which every part of the ether is subject, must be carr o with a velocity of the same order of magnitu le the velocity of light †

* Popular Astronomy

† Lodge, The Ether of Space (1909), pp 109-[illegible]

On this assumption Sir Oliver Lodge calculates that the ether must possess 3 10[14] kilowatt centuries per cubic millimeter or the energy of a million horse-power station working continuously for forty million years Kelvin s theory is based upon the principle of the gyroscope as applied to fluids which thus imitate solids Many experiments have been made to demonstrate the strange properties of liquids or flexible solids when in rapid motion. A silk cord moving swiftly over a pulley has become rigid and viscous and waves set up on the cord traveled with its velocity thus standing still This shows why "the speed of (the ether s) internal motion must be comparable to the speed of wave propagation" To show the elasticity of spinning bodies Lord Kelvin made a spring balance out of gyrostats* The hardness" of fluids in motion is illustrated by a stream of water under strong pressure which will resist blows from a sword.

Kelvin s gyroscopic theory however is useful only in providing a fluid ether with the elasticity of a solid And does it not seem futile to evolve an ether from the properties of matter when those properties in turn depend upon the ether? The action of the gyroscope involves the inertia of matter yet Prof J J Thomson and others are now inclined to explain inertia as an effect of the electromagnetic energy which a body carries about with it in the ether But if inertia is not an inherent" property of matter but rather a phenomenon involving ether why should it be used to endow the ether-particles? A second ether would be necessary to account for the inertia of the first Indeed it is so difficult to build up any hypothesis without the use of inertia and the laws of motion that we may be compelled at last to resort to another ether But since that is merely shifting the ultimate problem we must do our best to gain a simpler theory

Again it is difficult to conceive how the particles however fine grained their gyroscopic motion would avoid being in continual contact and collision destroying the permanency of the system and producing a gaseous state Motion in exact circles would be broken up and the gyroscopic principle no longer at work At least it is difficult to explain how any kind of motion can be provided for the crowded particles of ether other than some irregular chaotic vibration like that of a gaseous molecule The particle cannot be compared to the vibrating molecule in cohesive solids nor to the revolving electron for both must be held in their systematic orbits by forces acting through a medium The difficulty of making the ether circulate about a fixed center in order to make it gyroscopic and elastic seems about as large as the original problem itself

There are perhaps other ways of explaining the properties of rigidity and fluidity in the ether If matter be regarded as merely a crack or strain in the ether the latter need not be fluid since there could be no such thing as friction between matter and ether Then if the ether be thought of as quite densely packed with particles in orderly rows, columns and tiers it might not be difficult to imagine how a single pulse of light emanating from a molecule should continue like a missile having inertia to follow the straight line upon which it was started. For light is made up of waves in several planes which we may regard separately Motion in one plane cannot pass into another and if the tier of particles in which the wave started is not disturbed by passing matter the wave would remain in one plane But what prevents the wave from spreading about its plane instead of holding a straight path? This too must be a result of the regular arrangement of the particles, so that the wave moves as a uniform interaction among the particles of several rows confined to these rows alone, like a moving pendulum. Thus the simple pulse from a molecule in the Sun would reach our Earth practically unchanged The size of an object then, alters not because all the mingled pulses reach the eye diminished in size but because the number o pulses entering the eye undiminished depends upon the square of the distance Were the former the case and if the light-wave spread out like a sound wave as it emanated from a source some change in the structure of wave would take place and it would be difficult to explain the rectilinear propagation of light. The structure of the ether could scarcely be as perfect as pictured but if the particles be of a very small order of size compared to the light-wave the result should be about the same Only by this [illegible] indeed could we imagine the tubes, or parallel rows traversed by each wave, as stretching away from the source [illegible]

* Address to Section A of British Association [illegible]

every direction This description, crude as it is, may serve to show that the theory of the ether has not yet been exhaustively worked while it points out some of the difficulties in an adequate explanation of the actual transverse wave in ether

Having reviewed some of the general theories of the ether it will be interesting to look into the methods which have been used to gain facts and figures in regard to the ether and to see what tangible results have been reached.

A modern school of physicists have derived a value for the elasticity of the ether from the formula $V = \sqrt{\frac{K}{D}}$ or $K = V^2D$ The density of the ether has been calculated on the assumption that the electron is a differential portion of ether but of equal density The linear dimension of the electron is about 10[-13] or 10[-14] millimeters, and if its mass is not an effect of its magnetic field the various estimates based upon different experiments all yield the same result, about 10[12] c.g.s. units V^2 we know to be 9 10[20] so that $K =$ 10[33], the figure generally agreed upon by some of the greatest scientists The estimate is of little value however except as it may direct further inquiry The structure of the electron must be investigated before its density can safely be used to indicate that of the ether

Deductions have been made as to the structure of the ether from the computed velocities of the various wave-lengths of light in space But they are of questionable value for at present it is still a moot question whether or not the various waves have exactly the same velocity However it is an important line of research and will certainly yield us some knowledge of the ether We are too accustomed to treat light as a whole not as to particular wave-lengths Lord Rayleigh has said We have no means of identifying a particular wave so as to determine its rate of progress What we really do in most cases is to impress some peculiarity it may be of intensity or of polarization upon a part of an otherwise continuous train of waves and determine the velocity at which the peculiarity travels Rayleigh used the formula

$$U = \frac{d(kV)}{dk}$$

to express the possibility that V the velocity of a particular wave-length may differ from U the group velocity Now the work of Nordmann on Algol has tended to show that red rays (about 0 68μ) were sixteen minutes ahead of the blue (about 0 43μ) Pritchard s estimate of Algol s parallax is 0 0556 second or about 61 light-years Dr C V Burton using these data and Rayleigh s formula (L. E D Philosophical Magazine December 1909) has set up equations representing the conditions of periodic motion in the ether, in order to show that the velocity of propagation is a function of the wave-length and that no absorption need occur in the ether The laws of dispersion are applied to strings and by combination of these to three-dimensional space. The nature of the formulæ developed by him leads to the conclusion that "The system (of ether-particles) has a structure on a scale not infinitely minute compared with the wave-length Though we may conceive the electro-magnetic vibration of the ether to be executed in a manner widely different from anything occurring in these simple mechanical models we may yet attempt to form some idea of the coarseness of structure of the ether which could suffice to account for such dispersions as Nordmann and Tikhoff have thought to be indicated by their observations. The formula deduced by Dr Burton from Rayleigh's equation is $U = V_0$ $(1 - \pi^2b^2)$ [illegible] When this is applied to the figures given by Nordmann and Tikhoff above, the result is only 1 7 10[-4] centimeters and 3 1.01[-4] centimeters, respectively for b "a linear magnitude which expresses the coarseness of structure of the ether." But the electron is said to be only 10[-13] centimeters in diameter; and since the ether-particle should be of a lower order of size than the electron, this indicates that the observations are unreliable or the formula wrong. The fact that the two observations disagree in the ratio of nearly one to thirty has furnished an argument against the reality of dispersion. But if dispersion is proved to exist it must be attributed to the structure of the ether, since Lebedew has shown that it cannot be accounted for by the presence of any known substance in space (for example, hydrogen at low pressure) which would absorb [illegible] [illegible]

meter for full sunlight; and a quarter of a century later Lebedew, Nicaeis, and Hull verified the theory, the two latter reaching a figure within one per cent of Maxwell's estimate. Lately Prof. Poynting has measured the backward thrust of the light-wave as it leaves its source When we have worked out a definite picture of the electro-magnetic wave this primary fact should be very useful in explaining its genesis and the relation of the electron to the ether surrounding it.

It has been assumed, during the above discussion that no friction exists between matter and ether but the question was by no means settled until recent years Many experiments were tried during the past half century, but none were conclusive until Michelson made his famous experiment in 1887 This seemed at first to show that the ether is stagnant about the Earth or that it does not rush by us and through us at the rate of the Earth's motion Two half beams of light, one sent to and fro along the line of the ether drift, east and west and the other across the line of drift, were reunited and should have shown a displacement in the bands of the spectrum of one part in a hundred million—the square of the ratio of the speed of the Earth to that of light A change of one part in 4 000 millions could have been detected in the apparatus but no change was seen The explanation was first suggested by Prof G F Fitzgerald of Trinity College, Dublin, and was later developed by Prof H A. Lorentz of Leiden. The cohesion of the materials in the apparatus by which the measurements were made was probably due to electric charges in the atoms. The cohesion was then less great across the line of the Earth's motion than along it for the reason that the charges become currents on account of the Earth's motion, and the attraction between the parallel currents is less than in the currents which follow each other in the same line of motion Therefore although the light wave probably increased in velocity across the line of the Earth's motion the stone slab across which it traveled increased in length proportionately

An interesting and original experiment was undertaken by Sir Oliver Lodge to settle the question in a different way Two large steel disks an inch apart were rotated at enormous speed while a beam of light was divided by a semi transparent mirror and the two halves were sent in opposite directions around and between the disks until they met in a telescope After eliminating the sources of error it was found that the images were exactly coincident and that hence no ether had been caught up in the motion of the steel disks

Perhaps nothing has contributed so much to the possible development of a theory of the ether as the electron theory which has done so much to reduce phenomena to the inter play of the electro-static magnetic and inductive forces of charged atoms These forces together with matter which may be simply their source in the ether and gravitation which is probably an electro static effect constitute the whole problem of the ether The ultimate task is to explain them as the varieties of motion in the fundamental stuff

To sum up it is apparent that the problem of the ether the greatest enigma of all time cannot be solved by one group or generation or class of scientists It claims the work of specialists in many fields While each may see the task from his viewpoint alone it is worthy of attack from many standpoints To analyze and classify a nearly infinite variety of phenomena to reach the root causes of nature requires the genius of the investigator To arrange the data in the most logical relationships requires the work of the theorists To condense and reduce these relations to the simplest and most elegant form the brain of the mathematician is necessary To appreciate the ultimate significance of those factors which the others use but as the material of their building the philosopher is final critic And to make the results of all the others of interest and value to the human race as a whole the interpreter must picture them in simplest phrase and most apt illustration

Do Fishes Hear?

A Summary of Recent Studies

By Dr Wilhelm Roth

Although Saint Anthony of Padua preached to the fishes this is no proof that the fishes heard him for the holy man preached to many deaf ears An other ecclesiastical tradition which has often been cited in evidence of the auditory power of fishes has likewise failed to stand the test of critical investigation

The famous old Benedictine cloister of Krems in Austria, possesses a monumental fish pond surrounded by stone balustrades and arcades whose finny denizens have from time immemorial been summoned to their meals by acoustic signals—in the old days by beating a drum and in modern times by ringing a hand bell

Dr Alois Kreidl who had previously expressed the opinion that if the fishes really come in response to the ringing of a bell tney do so because they feel the vibration not because they hear it recently visited the monastery in company with Prof Exner the well known Viennese physiologist The investigators easily proved that the fishes did not hear the sound of the bell but came to the feeding place only when they saw the attendant ring the bell and throw out the food or when they felt the vibration communicated to the water by the man's footsteps on the stone run of the pond When the two observers approached the feeding place in such a manner that the fishes could not see them hid behind a column and there rang the bell the fishes did not take the slightest notice of the sound but when they came to the feeding place in the customary manner of the attendant without ringing the bell the fishes quickly swam to the spot. They dispersed immediately on finding that no food was forthcoming and could not be recalled by ringing the bell.

A similar explanation can be given of many other instances in which fishes are apparently attracted by the sound of the human voice of bells attached to fishing nets of drums and of the clappers which the Japanese employ in conjunction with torches in fishing with cormorants Kreidl and Exner found it impossible to elicit from goldfish any response to whistling the peal of a large bell and various other sounds generated in the air or even to tones produced by drawing a violin bow over metals bars under water Another experimenter obtained the same negative result with the ear splitting noise of the toy known as a cricket

Even when the reflex irritability of the fishes was greatly increased by dosing them with strychnine they responded only to sudden and violent sounds like that of a pistol shot which caused them to flee in terror As Langes and Vulpian have found that a pigeon which has been deprived of its brain and therefore of its sense of hearing responds to a pistol shot it appears probable that violent explosive noises affect the nerves of touch or feeling by means of the concussion of the air which is transmitted to fishes through the water

In order to prove decisively whether the reaction in the case of fishes is accomplished by any true auditory sensation or is caused entirely by mechanical stimulation of the tactile nerves Kreidl experimented with fishes from which the labyrinths of both ears had been removed These fishes reacted to very loud sounds in precisely the same manner as unaltered fishes when both had been dosed with strychnine

Hence there can be little doubt that in fishes the surface of the body has assumed the auditory function and that a perception of vibrations by the tactile nerves takes the place of a true sense of hearing It is natural to assume that in fishes the organs of the so-called lateral line which are sensitive to the slightest change in pressure correspond to the cochlea of higher vertebrates with its Corti's fibers which parts are entirely absent from the ears of fishes

We are not justified however in assuming that the ears of fishes play no part in the perception of vibrations produced by sound waves for the otoliths of the labyrinth may serve in fishes as they do in many other aquatic animals for the perception of vibration and may thus assist the organs of the lateral line of the body It is probable indeed that the labyrinth of the ear is only a highly developed and specialized lateral organ and according to Bonnier the perception of mechanical vibration is simply the initial stage of the sense of hearing The difference between the two functions is that in the former the vibrations of pressure are perceived separately while in the latter they are fused into a single tone as the mosaic image formed on the retina is seen as a single picture

Although the fishes that have been studied appear to possess no true sense of hearing it is not impossible that the ears of some fishes have acquired some slight development There are many fishes about 80 species which produce sounds In the pairing season some fishes fill the water with noise which can be heard plainly by an ear pressed to the ship's side Whether these sounds are produced voluntarily (perhaps to attract the opposite sex) or not is wholly unknown but even if some of these musical fishes are found to be sensitive to sounds of moderate intensity it will still remain probable that they perceive these sounds by a sense of vibration akin to the sense of touch and do not really hear them —Translated for the Scientific American Supplement from Umschau

The Transformation of Sea Water Into Fresh Water

The belief was prevalent among the savants of the 17th and 18th centuries that a hermetically sealed earthen vessel dipped into the sea would fill itself with fresh water At the present day it is difficult to say on what this belief was grounded It surely could not have been evoked by experiment. In a similar sense Marsigli, the founder of oceanology made in the year 1706 an experiment which effected the filtration of sea-water through a system of fifteen pots filled with washed garden-earth or sand and so placed as to let the water fall as if in a cascade It is stated that the palate disclosed a definite diminution of the presence of salt. Similar assertions are everywhere current among seamen.

A scientific test of the endeavor to free salt from water was recently made by the French investigator [illegible]. His report which appears in the minutes of the Académie des Sciences of Paris states that the [illegible] of salt can be reduced by filtration. Forty [illegible] of the length of a glass tube, which was [illegible] long and was placed in a perpendicular position [illegible] with [illegible] the rest of the tube [illegible] of the alkalis were [illegible] to ascertain the density and chemical composition The result was that in the initial stage of the experiment density as well as saline content were found to be moderately reduced very soon thereafter both recovered their original value The early decrease of value is explained by the mechanical attraction which every chemically neutral body exercises on the molecules of a substance in solution as soon as the body comes in contact with the solution In nature too sand fails to effect the separation of salt. Through shipwrecked seamen it became known that relatively fresh water may be found on very low and barren coral reefs in the Pacific Ocean by digging to a trifling depth in the coral sand It is not however as was supposed sea-water freed from salt through the layers of sand but is simply rain water that is retained by a sandy stratum and by it protected from admixture with the sea water Similar phenomena may be observed on the European coasts They may be considered the key to the popular belief now contradicted, that sea water can be sweetened by filtration through sand

Mr W Rosenhain, a well-known English metallurgist, in a report of the Advisory Committee for Aeronautics, reviews the results of researches on the alloys of aluminium containing small quantities of other metals so as to leave the density of the alloy very nearly as low as that of the pure metal and yet obtain the increased strength and hardness given to the alloy by such additions A certain number of these alloys are already in industrial use namely those containing Cu Ni Zn and Mg The mechanical tests of the Cu Al alloys containing 2 77 and 3 76 per cent of Cu are given and also the tests of two Cu Mn Al alloys containing respectively 2 per cent of Cu and 2 per cent of Mn and 3 per cent of Cu with 1 per cent Mn The elastic moduli of these latter alloys have been determined and are compared with wood The elastic modulus of wood is of the order of one-sixth of these alloys Some tests are given of Al Ni alloys which appear very promising but these are said by Guillet to easily corrode Some details are also given of the Al Zn alloys One of the most interesting of the Al alloys is known as wolframium or wolframinium which contains small quantities of Cu Sn Sb and W The alloys known as magnalium contain from 3 to 10 per cent Mg and it is claimed that they are 2 to 3½ times as strong as pure Al It is pointed out that there is a large field for possible improvement in the range of light alloys to be obtained by the addition of small proportions of heavier elements to Al.

Mixing Concrete on the Farm

How to Select Your Materials and Mix Your Own Concrete

On account of its cheapness uniformity and quick development of strength the only cement practically used at present is the kind called Portland There are almost as many brands of Portland cement as there are of wheat flour For farm work choose some brand guaranteed by the local dealer to meet the standard specifications of the American Society for Testing Materials which standards are approved by the national government

Cement takes water so easily that care must be exercised in storing it Upon the regular floor of a good building place timbers close together as a support for a false floor upon which the cement should be piled

Cement is heavy do not overload the floor of the building by piling it too high and do not store it against the side walls Keep it covered with canvas or roofing paper Cement once wet sets up and is unfit for use However lumps due to pressure in the storehouse must not be mistaken for set up cement Such lumps are easily crumbled and may then be used

Concrete is a mixture of Portland cement and particles of stone The stone should vary in size from pieces one inch in diameter to sand grains By so grading the stone the smaller particles fit in the spaces between the larger pieces thereby producing the most compact and the strongest mixture

The best stone for crushed rock is one which is clean hard and breaks with sharp angles Trap granite and hard limestone are among the best the use of shale slate and soft limestones and sandstones should be avoided The crushed rock should be screened on a ¼ inch screen to remove the fine particles These small particles should be considered as sand and if insufficient in quantity to make the proper proportion of the concrete as is described later enough sand should be added to them to produce the required amount

Gravel well graded in sizes is at least equally as good for concrete as crushed stone Bank run gravel just as dug from the pit seldom runs even and rarely has the right proportion of sand and pebbles for making the best concrete The mixture most suitable has one part sand to two parts gravel measured by volume in which all sizes passing through a 1 inch-mesh screen and retained on a ¼-inch screen are considered gravel As there is usually too much sand for the gravel it is both advisable and profitable to screen the material and to remix them in the proper proportions Gravel should have no rotten stone and should be clean so that the cement may adhere to it tightly

With dirty sand no amount of cement will make strong concrete Generally sand is clean but if not it can easily be washed by playing a hose or flushing water upon thin layers of sand placed on a tight-jointed inclined wooden board In size of grain it should vary uniformly from fine to coarse All particles passing a ¼ inch screen may be considered sand Any good tasting drinking water is suitable for concrete

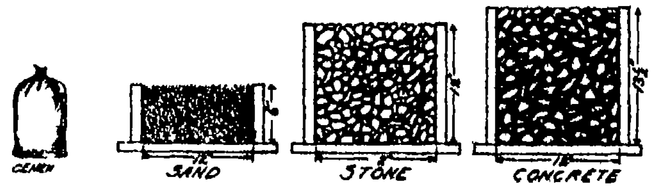
The tools and equipment necessary for making concrete in moderate quantities are already at hand on a well conducted farm or will be useful afterward for other purposes The list comprises the following and is shown in the illustration herewith

2 square-pointed paddy shovels No 3
1 round pointed tiling shovel or 1 garden spade
1 heavy garden rake
1 sprinkling can or bucket or 1 spray nozzle for hose
1 water barrel or 1 length of hose
1 sidewalk tamper or home made wooden tamper
1 sand screen made of section of ¼ inch wire mesh nailed to a wooden frame.
1 measuring box or frame. See description further along in article
1 mixing board.
2 wheelbarrows with steel trays.

For farm work the following proportions are most suitable

For concrete necessarily waterproof 1 2 4 or 1 4
For all other ordinary purposes 1 2½ 5 or 1 5

Such proportions of three parts, as 1 2 4 indicate that the concrete is to be mixed 1 part cement to 2 parts sand to 4 parts screened gravel or crushed rock and 1 4 that it is to be mixed 1 part cement to 4 parts bank run gravel



SHOWING PROPORTION OF MATERIALS USED AND RESULTING CONCRETE

VIEW OF MEN SHOVELING AND MAN RAKING CONCRETE

SHOVELING CONCRETE ON A TWO MEN BOARD

CONCRETE MIXING BOARD TOOLS ETC

Measurement by counting shovelfuls is poor and uncertain practice To avoid splitting of bags of cement make as the unit of measurement 1 cubic foot the amount of loose cement contained in one cement bag Such measurements are made a very easy matter by gaging the wheelbarrows For this purpose use a bottomless box holding one cubic foot A shallow bottomless frame is also a convenient means of measuring Such a frame when set on the mixing board and filled should contain the *full* amount of sand or *one half* the quantity of gravel, or crushed rock required for one batch of concrete

The size of the batch is dependent upon the amount of help and the dimensions of the mixing board or platform For work of ordinary size sufficient room will be had on a two-men board 8 by 14 feet, framed solidly and covered with one-inch stuff with tight joints the short way of the board. A wooden strip nailed around the outer edges will prevent the loss of liquid cement For such a board and the proportions designated above make the bottomless frame of the clear dimensions given in the table below

Table for Two-Bag Batch

Proportions	Sacks of Cement	Framefuls of Sand.	Framefuls of Crushed Rock or Screened Gravel	Clear Dimensions of Frame
1 2 4 or 1 4	2	1*	2	0′ 6 × 2′ 8′ × 3 0′
1 2½ 5 or 1 5*	2	1	2	0′ 6″ × 3 6″ × 4 0″

*For bank run gravel use the same table, but no sand is required except that which is already in the gravel.

All the materials (slightly more than the computed quantities) should be on hand before beginning the work They can often be hauled at odd times. The sand and gravel or stone should be piled so as:

To cause the least amount of wheeling

To make the mixing most convenient to the water supply

To allow room for the future location of the mixing board

If the gravel does not need screening place a bottomless frame, previously described for a 1 4 mix, on the mixing board and fill it level with gravel. Lift the frame spread the gravel slightly with the garden rake, and upon it distribute evenly two bags (the full amount) of cement. Set the frame upon the leveled surface of cement and gravel and again fill it in the same way.

Remove the frame and spread the entire mass by dragging it back and forth with the rake. Two men, opposite each other, then [illegible]

until the cement no longer shows in streaks, the mixture has a uniform color Throw up the edges, and, with sprinkling can or hose with nozzle apply water in quantity according to special directions obtainable for each particular kind of construction Turn again and add as much more water as may be required If dry streaks are still evident, continue the turning until they disappear With wheelbarrows quickly remove the concrete and immediately use it in the work

If crushed rock or screened gravel is to be used fill the bottomless frame with sand and distribute upon it two bags of cement Drag the materials back and forth with the garden rake then turn as described above until the mass has a uniform color Spread the mixture so that two framefuls of crushed rock or screened gravel may be placed upon it. Wet the mass and turn as for bank run gravel until each stone is coated with cement mortar Remove as for the gravel concrete

For the proportion of 1 2½ 5 or 1 5 the method of mixing is the same

Since c ushed stone is more or less porous in dry hot weather it is advisable to keep the stone pile wet or at least to water the stone well as it stands on wheelbarrows ready for the mixing board

No vast amount of knowledge and experience s necessary to do first-class work in oncrete. Success is dependent upon the care and thoro ighness exercised in the

Selection of the materials

Mixing of these ingredients and

The Mathematical Initiator

A Tangible Multiplication Table

A FEW years ago a French gentleman named Camescasse constructed for the edification of his children a tangible multiplication table with the aid of the one-inch cubes of the Froebel kindergarten material He has recently improved this apparatus for teaching the rudiments of mathematics by using cubes with deep grooves on two opposite sides and at right angles to each other into which can be inserted straight bands of metal which fit the grooves tightly enough to hold a row of blocks together but not too tightly to be easily removed

The improved apparatus which is sold under the name of the mathematical initiator consists of 600 white blocks 600 red blocks and 144 metal bands of various lengths The blocks measure a trifle less than one centimeter every way so that a row of d blocks with the inevitable narrow interstices between them measures 10 centimeters very approximately The grooves are 5 millimeters deep and 0 8 millimeter wide and the longest metal bands are 4 millimeters wide, 0 8 millimeter thick and 92 millimeters long Hence a band which binds ten blocks together is completely buried in them and the blocks form a smooth

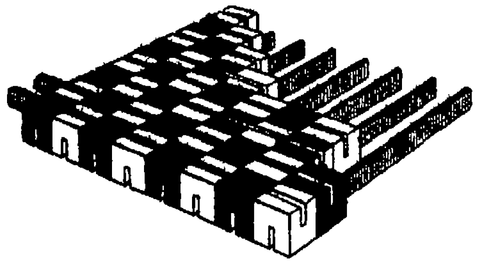

Fig. 1 —Method of assemi ling tl l locks by means of metal ban ls

square bar one decimeter in length By inserting bands in the other set of grooves ten of these composite bars can be joined together to form a plate one decimeter square as is shown in Fig 1

The mathematical initiator will be found useful in forming the designs and patterns which constitute a regular part of kindergarten work Fig 2 shows one of the vast number of patterns that can be formed of

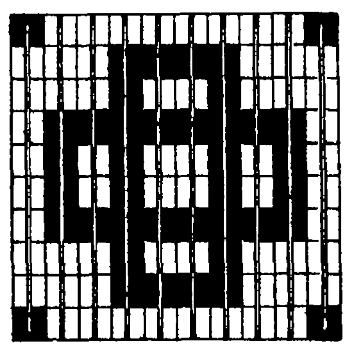

Fig 2 —A n osaic pattern

the red and white blocks assembled by means of the metal bands By handling the blocks children are unconsciously initiated into the mysteries of arithmetic and learn to count with hands and eyes before they can name or write the numerals A young child is soon taught to affix to each metal band one block for each of its ten fingers and the count can be verified by placing the fingers on the assembled blocks as on the keys of a piano Afterward the child learns to count the blocks and the bars of ten blocks Te bars of 10 can be assembled into a plate of 100 by inserting metal bands into two of the vacant grooves and 10 plates can be piled up to form a cube of 1 000 blo ks or one cubic decimeter In this way the child requires an objective knowle lge f units tens and hundreds and learns that a thousand represents 10 hundreds or 100 tens At the same time a familiarity with the metric system is acquired The child soon adopts the square centimeter as the unit of area and the cubic centimeter as the nit of volume and learns that a d imeter contains 10 centimeters a square decimeter contains 100 square centimeters and a cubic decimeter contains 1 000 cubic centimeters

More abstruse arithmetical operations can also be materialized witl the aid of he mathematical initiator Among such operations are those w ich give the squa e of the sum of n consecutive whole numbers the squa e of the sum or differen e of two numbers etc Fig 3 shows a square of red and white blocks arranged to illustrate tl e formula $(a + b + c) = a^2 + b^2 + c^2 + 2ab + 2ac + 2bc$ that is the law tl at the sq are of the sum of three nu bers is ob ained by adding the sum of the sq ares of the n l ers to twi e the s m of their prod ts taken two a d two I he example illustra d l e numbers are 2 and o the sum of which is ten A little inspection of Fig 3 shows that the large square having 10 blocks on a side is made up of three sn aller squares havi g resj ectively 2 3 and 5 on a side and of three pairs of rectangles of 2 by 3 2 by 5 and 3 by 5 but this fact is impressed on the

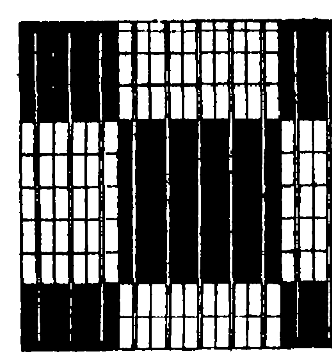

Fig 3 De str t on of formula $a + b + c) \quad a + b^2 + c^2 + 2al + 2ac + 2bc$

ch l l s mind far more firmly and in concrete form in the process of building up the large square The above ar ol ly a few of tl ed ational possibilities of the n athe atical initiator —Revue des Sciences

Problems of Existence

By Sir Oliver Lodge

IN the first of a series of three lectures just delivered on Problems of Existence Sir Oliver Lodge said that the term science might be used in a narrow or in a broad signification Sometimes the one was convenient but always the other was permissible and if the use of the term in the narrow sense tended to obscure the larger significance then in that connection such use must be deprecated It was rather commonly supposed that the region amenable to strictly scientific study was a narrow one and that it by no means embraced nor would it ever embrace the whole of possible knowledge A boundary was often drawn between tl e scientific arena, on the one hand and the literary the philosophic the religious domains, on the other But in truth no such bound ary could be drawn there were no absolute barriers or discontinuities in nature Every subject merged into, and had more or less connection with every other It was true that subjects were in very different stages of maturity more exact and precise knowledge was attainable in some of them than in others, Those subjects which in a given epoch of the world's history were susceptible of exact and demonstrative treatment—especially those which were amenable to the alternate analysis and synthesis of the Newtonian method—constituted the citadel of the scientific domain. But there were also sciences which, as yet, were almost wholly in the stage of observation and classification and any one of these might develop sooner or later into some thing more like the deductive stage as chemistry had within the last century—not only new compounds, but even new elements being predicted—and as biology had begun to show signs of doing under the stimulus supplied by the genius of Darwin and of Mendel There could be no doubt that this tendency toward advance from tl e vag e to the definite was a constantly progressive one and that departments f human experience now apparently beyond treatment by rigorous methods would gradually be incorporated and fused in the onq ered and explored territory Meanwhile they were not shut off from human scrutiny n erely because rigid treatment was not yet applicable They must be treated by methods appropriate to the stage to which our minds had risen with respect to them No contempt for such methods should be felt except when they were applied in departments wherein they had already been superseded

Some there were who regarded the scientific advance or as they called it, encroachment upon wild and unexplored territory with dislike thinking that the process would be death to mystery and would reduce all nature to matter-of fact and commonplace In geography it must to some extent be so sin e the surface of the earth was limited But those who realized the infinitude of complexity in the simplest existence and the way in which the whole of creation was bound together without barriers or bo nd aries or limitations forming one continuous and infinite whole would have no such fear nor would they think it inappropriate for a scientific man to cast his eyes around from time to time to see what new departments of knowledge might be coming within his ken Indeed they would not hesitate to welcome such advances and reach out a hand to catch as best they might some anticipatio of the interest that must thus legitimately accrue to the accumulated wealth of knowledge now within our grasp

THE PROBLEM OF EVIL.

The narrow specialising attitude was useful and had performed yeoman service. The work of the delver and digger was of tl e ut nost value but they must not through se and wont g adually acquire the notion tl at h rs was the only method of value or that the wo k of l e hun anist the inspired glea ns of the poet the g ides aval able tl ro gh the int ition an l l stin ts of humanity w re deceitful will o the wisps whi l led o nothing I'h re was room for every class of worker and tl e men of science themselves might in certain noods raise themselves out of their groove of steady work and look around as one and another had always done and tell the world what it was they saw from their point of vantage—whatever that point of vantage might be whether elevated peak or subterranean cavern For however it might be regarded by others still it was their point of view the place they had attained thro gh severe toil and it was not only their right but their duty to tel such other workers as would listen what it was that thence they saw

Sir Oliver elaborated a reasoned foundation for an optimistic attitude toward the Universe dealing with the Problem of Evil as illuminated and to some extent solved by the relativity of all things He instanced the analogy of light and shade in an engraving and pointed out how meaningless and monotonous existence would be if it were all high light He considered that pessimism if encouraged led to a kind of practical atheism and that this attitude was quite unnecessary and illogical In his treatment of evil he discriminated however between the theological problem of evil in the abstract and the h mai problem of sin or man made evil and insisted that an explanation of the one formed not the slightest justification for the other thoug by casual readers and speakers the two aspects w re sometimes confused —English Mechanic and World of Science

Marconi's Marvels Explained in a London Law Court

Messages Received in Court from Ships at Sea

By P. F Mottelay

On Monday the 12th of December was commenced in the Chancery Division at the London Law Courts before Mr Justice Parker one of the most interesting suits on record also likely to prove one of the most costly by reason of the large number of eminent counsel employed as well as of the many expert witnesses to be called and of the long time it will necessarily require to properly bring before the court all the claims of the litigants

The action is brought by Mr G Marconi and his companies against the British Radio Telegraph and Telephone Company for the alleged infringement of three patents dated 1900 1902 and 1907 Representing the plaintiffs are Mr Astbury K C Mr A J Walter K C and Mr J H Gray For the defendants are Mr T Terrell K C and Mr Colefax All the lawyers employed are well specialized in patent law

The wireless system is to be worked in court by means of the Law Courts electric current which has been tapped by leave of the Office of Works under the supervision of Prof Boys A wire attached to the complicated machinery passes through one of the windows and connects with an aerial wire fixed to the clock tower It is said that messages will be interchanged with stations at Gibraltar in the Mediterranean and elsewhere and with ships in the English Channel Some messages had already been picked up over London when the apparatus was set up the previous Saturday

The whole of the first day was devoted to Mr Astbury's opening speech which was not concluded until middle of the day following He explained that his address would be divided into four parts in an endeavor

1 To show what Mr Marconi had done apart from scientific theories

2 To put the court into possession of the scientific theories connected with this very difficult system and explain what was scientifically known before granting the patent of the four sevens

3 To explain the four sevens patent

4 To deal with the question of infringement

He then gave a short sketch of the history of wireless telegraphy describing the first beginnings of knowledge and traced the results which were obtained by Heinrich Hertz the great founder of the whole theory upon which the system has been built up and mentioned the fact that Sir William Crookes was the first who suggested the possibility of using Hertzian waves for the purpose of transmitting messages This he did in a Fortnightly article published during 1892 Two years later (1894) Sir Oliver Lodge gave a lecture at the Royal Institution of Great Britain which was by many relied upon as an anticipation of Mr Marconi's 1900 patent but erroneously said he for Lodge made no satisfactory suggestion as to how the Hertzian waves could be put into practical use, he had deflected a galvanometer needle from the distance of a few yards, and all that he had really demonstrated was the existence of the ether waves

During 1896 Mr Marconi took out the first patent ever granted on wireless telegraphy He made numerous trials and succeeded in transmitting messages in Italy a distance of 1¼ miles and, on Salisbury Plain in presence of many British officials as far as 1¾ miles In the following year, at the last named place he sent messages first 4 miles, then 8 miles, across the Bristol Channel subsequently increasing the distance to 12 and to 14 15 miles and finally covering 30 miles during the year 1899 The year before (1898) the wireless system had been installed between Osborne and the royal yacht, thus enabling Queen Victoria to maintain constant communication with the then Prince of Wales (King Edward VII) In 1899 the system was fitted on three English battleships and was sent out to the Boer battlefields as well as to the Sandwich Islands In 1900 wireless was adopted by the Norddeutscher Lloyd Steamship Company and installed on one of their largest vessels In 1901 the Admiralty obtained a license for the use of wireless telegraphy from the plaintiff company, which had four years previously been registered to take over and work Mr Marconi's patents in Great Britain It was in this same year (1901) that the wireless was accepted by the Canadian government and that the first message was transmitted from Poldhu in Cornwall to Newfoundland some 1 800 miles, which distance was increased the year after to more than 2 000 miles In 1903 an International Conference was held in Berlin at which England was represented but in consequence of England's relations with the Marconi Company that country could not assent to certain definite propositions put forward by the other nationalities

During 1904 the Wireless Telegraphy Act was passed mainly to enable the making of international agreements It prohibited the installment of the system in the United Kingdom or on British ships without the license of the Postmaster General and specified that the apparatus must be of the character described in the agreement that it must be syntonized in all British vessels that it must be so constructed as to be capable of using wave lengths of 300 meters—so as not to interfere with the longer wave used by war ships—and that the speed limit should not be less than twelve words a minute In the same year 1904 the Russian government ordered the wireless for its own purposes and used it throughout the war with Japan

Every important land station in the United Kingdom except one in Galway and one in Cornwall belonging to the Post Office, had meanwhile been prepared for the reception of the system, and during the year 1905 an arrangement was made by which the Board of Trade and the Corporation of Trinity House fitted lightships with wireless installations for the purpose of protecting the coasts. By a later agreement, it was arranged that the Post Office should acquire the land stations then being erected in order to prepare them for the transmission and reception of wireless messages. At the present time, every English battleship is fitted with the Marconi system, and not long since a message was transmitted to England from South Africa, a distance of 6,000 miles.

Mr Astbury explained how in the first half of the last century, phenomena relating to electricity were observed and gradually understood until, in the fifties, Joseph Henry first evolved the theory of oscillatory discharge of electricity, which was proven by Lord Kelvin then how Clerk Maxwell had evolved from the discovery of oscillation the newer theory that oscillatory discharges of electricity must be accompanied by wave disturbances in the ether which theory he showed was satisfactorily proven by Hertz and others Tesla, he said was the first man who drew attention to the utilization of air waves, and he then explained Lamby's invention of the coherer, by which the waves were controlled and measured and he also reviewed all other improvements made up to the present time.

By way of illustrating the principle of "the four sevens" patent (No 7 777) of 1900 Mr Astbury said that if you kept on giving a pendulum little touches with a feather you gradually get it to take long swings In the same way little waves were seen pattering up against the 'four sevens' receiver When their combined efforts reached the point to which it was tuned the messages were read. By this device messages got to their intended destination and nowhere else

With regard to the infringement, Mr Astbury argued at great length how the defendants had imitated Mr Marconi's patented apparatus, with the exception of the unimportant transformer by employing the same persistent oscillator the same aerial and the same primary in a closed circuit. He alleged that the defendants had copied Mr Marconi in every thing they had done

In conclusion, Mr Astbury stated that the two great problems Mr Marconi had had to face were

1 How to improve his apparatus so that each receiving station should respond solely to the waves from one particular transmitter or set of transmitters.

2 How to increase the efficiency of his apparatus so as to cover great distances

The Origin of Bulldogs and Pugs

The history of most of our domestic animals is shrouded in mystery The breeders of former times did not realize the importance of keeping records of their methods and results or they were too ignorant to understand just what they were doing getting results for the most part through an occasional lucky hit amidst many routine misses

A German investigator attempts to work out the history of the bulldog and of the pugdog by studying the pedigrees of dogs goats pigs and cattle that showed the characteristic shortening of the skull that distinguishes these breeds of dogs After considerable comparative study of the skulls of these mammals he concludes that inbreeding is the cause of these peculiar head formations

This view is severely criticized by biologists since it is a well known law that inbreeding never creates new characters but only intensifies old ones A more reasonable view is that which directs attention to the fact that many wild animals when caught young and brought up in confinement do not have as long heads as shown by other members of the species in the wild state A decided shortening of the bones of the face takes place in the case of the wild dogs and the wolf This is the beginning of the pug face Inbreeding develops this character It is the *method* not the *cause* says Prof Hilzheimer of Stuttgart. This scientist finds the cause rather in the modified use of the jars resulting from conditions of captivity The face he says fails to develop the same as it would in a state of nature.

The bending of the bones of the palate in these dogs is explained by the upholder of the inbreeding theory as resulting from degeneration or rachitis (rickets) due to the inbreeding Prof Hilsheimer explains this bending as due to the crowding of the teeth consequent upon the shortening of the face bones

While it is true that inbreeding can not cause the appearance of a new character it is also true that we have no evidence of any character arising as a result of changed external conditions being preserved by heredity If it is true that changes in the food have made the jaws of wild dogs under domestication fail to development, we should be able to get the original wild dog again by suitable feeding this however is impossible According to our present knowledge the probabilities are that short faced dogs like short-faced varieties of other animals arose as "sports" and were preserved through inbreeding or even had the character intensified

The Diseases of Tea

The cultivation of the plant is making considerable progress in the Caucasus region and although its introduction has been comparatively recent, it has already brought a good profit to the planters. However the tea plant is subject to maladies caused by certain parasites which prevail in these regions. A Russian scientist, M. Spiechneff, observed twelve cryptograms, and one of them, the *Pestalozzia guepini*, causes a curious disease known as the "gray malady Here the leaves show gray spots surrounded with a border of darker color. After some time there appear small dark spots which represent the fructification of the fungi. Other dangerous species are the *Dicosia Theae* and the *Capnodium footii*. This latter causes a malady known as "soot" of the tea plant, and sometimes gives much damage. Another disease is described by M Spiechneff, and it has the form of buff gray spots sometimes covering all the leaves He considers that it is caused by a cryptogram but Duconnet and others consider that the disease is not of a parasitary nature The gray malady and the soot disease attack also the leaves of evergreen plants such as the camelia, rhododendron, and magnolia, but on the contrary the former hardly ever attacks any but the Chinese tea plant, and others escape it. We may also mention that M. Voronoff observed in the Imperial plantations near Batoum, a caterpillar which bores galleries in the young tea shoots and causes much damage in this way

A Berlin inventor has recently designed a simple device for the felling of trees. The trunks are cut by the friction of a steel wire about 1 millimeter in diameter which as demonstrated by practical tests, is able to cut through a tree about 20 inches (50 centimeters) in thickness in six minutes. The wire, which is carried to and fro by an electric motor, is heated by friction on the tree to such an extent as to burn through the timber, the result being a cut which is both smoother and cleaner than that effected by saw The wire will work satisfactorily on the thickest trees without the insertion of wedges into the cut, and the trees may be cut immediately above or below the ground. In the latter case the stump may be left safely in the soil. The motor which actuates the wire is placed outside of the range affected by the fall of the tree, and when electricity is not already available it can be generated by a transportable power plant consisting of a 10-horse-power petrol motor and dynamo, which are left at the [illegible] during the felling operations.

INDEX OF INVENTIONS

For which Letters Patent of the United States were Issued for the Week Ending December 27, 1910.

AND EACH BEARING THAT DATE

[See note at end of list about copies of these patents.]

Abrasive machine, Blevney & Hausman 980,054
Acetylene-generators, carbid-feeder for W K. McLeod 979 882
Acid oxalate and making same, vanadium, Mehlander 979,887
Adjustable bracket for furniture etc B. E. Beyer 980 049
Aeroplane controlling means P Daniel 980 073
Air lift, automatic chemical A Long 979,987
Airship of the rigid type, J Masschu 979 979
Alarm. See fire alarm.
Albumen preparation for albuminoids and salts of guaiacol sulfonic acids. A. Busch 979 646
Alkali solution for paper makers use apparatus for providing, S Hardman 979 483
Ammunition bar safety, R. J Routledge 980 009
Annealing furnace J L. Butler 979,435
Anvil belt, D Larson 979,519
Automatic and independent brake combined C. F Cain 979,939
Automatically operated gate, J T Walston 979 613
Automobile driving and supporting wheel F H. Breed 980,065
Automobile emergency brake automatic R. Eisalt 979 958
Automobile lamp operating mechanism automatic J H Butterfield 980 069
Automobile wheel J M Gilbert 979 466
Automobiles etc gasoline supplying attachment for, C. Eachow 980 041
Awning L. Rombaut 979 506
Bale or package tie E. Walden 980 136
Baling press, T H Diserens 979 650
Bark from wood separating F W Ayer 979 914
Barrette, E. C Gilnes 979 471
Bath tub, folding R. L. Leo 979 973
Bearing L. E. Palmer 979 881
Bearing antifriction, E S Woods 979 727
Bearing cage, ball, E Mitser 980 062
Bearing, roller H Hess 980 101
Bed and chair, combined F G Gale 979 461
Belt loop J L. Fredlihp 980 175
Belt stretcher F Thomas 979 599
Bench dog T W McCormick 979 528
Binding machine J Kellner 979 962
Bicycle lock R E Eggleston 979 453
Bill [illegible] frame H I Cowan 980 070
Bill holder and coin purse D O Snyder 979 808
Binder hitch J Kuts 979 700
Binder or loose leaf holder temporary Wiginton & Hodges 979 602
Binder or loose sheet holder temporary F L. Impey 979 673
Bits and drills, receptacle for O R Milke 979 981
Block. See building block
Block signal system G S Pflasterer 979 838
Boats, message carrier for, F J Meno 980 176
Bobbins, machine for applying split rings on the butts of D S Courtney 979 488

A printed copy of the specification and drawing of any patent in the foregoing list or any patent in print issued since October 4th 1859 will be furnished from this office for 10 cents, provided the name and number of the patent desired and the date be given. Address Munn & Co. Inc 361 Broadway New York.

Canadian patents may now be obtained by the inventors for any of the inventions named in the foregoing list For terms and further particulars address Munn & Co. Inc 361 Broadway New York.

Aeronautical Notes

Louis Blériot says high speed is dangerous and suggests a parachute life saver for aviators

The Journal has fixed June 4th, 1911 for the start of its circuit Paris Berlin Brussels London Paris

The newest Zeppelin, No IX," is very nearly finished It is only 430 feet long as compared to the 490-foot No VIII and the 420 foot No VII

Throughout France in retrospect of the year s progress, the words of Wilbur Wright at Auvours in 1908 are recalled These Frenchmen fly like hens chased by a dog"

The French monoplane constructors are beginning to realize the importance of building their machines so that the pilot can have a clear view on all sides and especially under him

The Wright machine of Count de Lambert which was recently fitted with a 50-horse-power Gnome engine has been ma[illegible]ellent flights at a higher speed than th[illegible] Wright.

Many of the fo[illegible]n aviators who fly Blériot monoplanes have two sets of wings for the same body one for lifting is large and quite curved while the other for racing is much smaller and very flat

The 'reefable-surface" aeroplane, which many experts consider one of the greatest developments we may in future expect seems already to be an actuality in France the Delabrosse and Christolet monoplane is so constructed that the outer sections of the planes fold back and reduce the speed from 29 7 feet to 23 1 feet

The Parseval hydro-aeroplane has created a great deal of interest abroad On October 15th it flew about three miles over Lake Plau at Mecklenburg, and when landing upon the surface of the lake was slightly damaged

Up to the 1st of December the winnings of Frenchmen in aeroplaning totaled three and one-half million francs Paulhan leading with 410 862 ($79 296) and Morane and Latham following him with about 260 000 ($50 180) each

The Astra concern are busy on two new dirigibles for the French army They are to be named the Adjutant Reaux and the Lieut Chauré They are each fitted with two Pipe 4-cylinder 110 horse-power motors driving three propellers one at the front and the other two on either side above the nacelle amidships

There are many new types of monoplanes in France noticeably the Sommer the Morane-Saulnier and the Minima The Morane monoplane greatly resembles the Blériot XI *bis*, it has a span of 32 feet, weighs 400 pounds and uses a 50 horse power Gnome motor The Minima built by the Société des Vehicules Aerien weighs only 120 pounds without the motor and has a spread of but 20 feet A 15 horse-power Anzani motor is employed

Trade Notes and Formulæ

Wax Ink for Zincography.—Carefully melt over a coal fire 3 parts of Syrian asphalt, 1 part wax, 1 part ceresine 1 part colophony 2 parts American rosin take the mixture from the fire and mix in 20 parts of oil of turpentine stirring in the meantime. To be kept in well stopped bottles.

Pipe Covering—1 5 parts syrup 2 5 parts rye flour, 10 parts loam 5 parts cows hair 50 parts fossil meal (kilselguhr) and sufficient water Over the strata applied layers of fabric are laid which are coated ¼ of an inch (5 millimeters) thick with a mixture of tar and lime (100 parts hot tar) into which is stirred 15 to 30 parts of slaked sifted lime powder

Preparation of Wax Powder—Yellow bees wax is cut into very fine shavings and protected from dust, and dried at ordinary room temperature for 10 to 14 days The wax must then be mixed in a mortar having a rough surface with an equal quantity by weight of rice starch. The mixing is effected at the lowest possible temperature without rubbing The powder mixture is finally passed through a fine tin strainer

Insulating Covering for Steam Pipes (according to Dietrich)—The cleansed pipes are coated with a priming coat consisting of 200 parts liquid water-glass, 100 parts of water 150 parts fine sand and 30 parts sifted sawdust. The covering mixture comes next, 60 parts of dry loam 8 parts sifted sawdust, 3 parts ground cork refuse, 4 parts potato starch, 4 parts potato dextrin 4 parts powdered water-glass 30 parts of water The loam must be well kneaded up with the water and add to this the previously mixed pulverized substances The paste-like mass is then spread with a trowel on the heated and primed metal surfaces, to a thickness of 3/16 to ⅜ of an inch (5 to 10 millimeters). When this layer is thoroughly dry the top coating can be repeated, until the pipe covering has a total thickness of at least two inches (50 millimeters) Previous layers must always be allowed to dry thoroughly To give a smooth finish to the final coat it must be brushed over with water, while still wet.

MECHANICAL MOVEMENTS

Powers and Devices

By GARDNER D HISCOX, M. E.

Size 6¼ x 9¼ inches. 403 pages. 1,786 illustrations. Price, $2.50, postpaid

THIS is a collection of 1 786 specially made illustrations of different mechanical motions, accompanied by appropriate descriptive text It is practically a dictionary of mechanical movements, powers, devices and appliances and contains an illustrated description of the greatest variety of mechanical movements published in any language This work covers nearly the whole range of the practical and inventive field, and is of much value to inventors, draughtsmen, mechanics, engineers and all those interested in any way in the devising and operation of mechanical [illegible] of any description. The book is divided into eighteen sections or chapters in which the subject matter is classified under the following heads: Mechanical Powers, Transmission of Power Measurement of Power Steam Power Steam Appliances, Mo[illegible] Power Hydraulic Power and Devices, Air Power Appliances, Electric Power and Construction Navigation and Roads, Gearing Motion and Devices Controlling Motion Horological Mining Mill and Factory Appliances Construction and Devices, Draughting Devices, Miscellaneous Devices.

MECHANICAL APPLIANCES

Mechanical Movements and Novelties of Construction

By GARDNER D HISCOX, M. E.

Size 6¼ x 9¼ inches. 396 pages. 970 illustrations. Price, $2.50, postpaid.

THIS is a supplementary volume to the one on mechanical movements. Unlike the first volume, which is more elementary in character this volume contains illustrations and descriptions of many combinations of motions and of mechanical devices and appliances found in different lines of machinery Each device is illustrated by a line drawing with a description showing its working parts and the method of operation. This volume contains 970 illustrations classified in twenty-three chapters, as follows Mechanical Power Lever, Transmission of Power, Measurement of Power Springs, Generation of Power, Steam Power Appliances, Explosive Motor Power and Appliances, Hydraulic Power and Appliances, Air-Power Motors and Appliances, Gas and Air-Gas Devices, Electric Power and Devices, Navigation Vessels and Marine Appliances, Road and Vehicle Devices, Railway Devices and Appliances, Gearing and Gear Motion, Motion and Controlling Devices, Horological Time Devices, Mining Devices and Appliances, Mill and Factory Appliances and Tools, Textile and Manufacturing Devices, Engineering and Construction Miscellaneous Devices, Draughting Devices, Perpetual Motion.

Special Offer • These two volumes sell for $2.50 each but when both are ordered at one time, we send them prepaid to any address in the world on receipt of $4.00. You save $1.00 by ordering the two volumes at one time.

Riddles of Science—New Elements in Chemistry

A Popular Talk by Sir William Crookes

By the English Correspondent of the Scientific American

At a recent dinner of the Authors Club of Great Britain Prof Sir William Crookes FRS the eminent chemist gave an interesting popular address on New *Elements in Chemistry* *In the length of his* discourse he traversed some of his own remarkable contributions to our knowledge of physics and chemistry and how such have influenced the modern trend of scientific investigation He pleaded guilty to much speculation on the nature of those complex variable and elusive mysteries that science has been accustomed to call elements

Before the eighteenth century he remarked the idea of elements was not much removed from the earth air fire and water of Empedocles—termed as the rational units and he proceeded to show that the ancients in their crude classification were not so remotely removed from the actual truth as appeared at first sight In the eighteenth century when modern conceptions of chemistry first dawned on the scientific mind the credulous chemist accepted the elements as ultimate facts In the nineteenth century scientific men gravely doubted and asked for proof of what hitherto had been taken for granted Obvious explanations he pointed out were seldom the true ones for simplicity was not a characteristic of Nature For nearly a century men of science had been dreaming of atoms molecules ultramundane particles and speculating as to the origin of matter This dream had been essentially a British dream and toward the end of the nineteenth century the notion of impenetrable mysteries was dismissed To-day we were confronted by problems and speculations concerning the ultimate constitution of the bodies we named elements

In 1879 he advanced a theory which has now been accepted that in the phenomena of the electric cathode stream we were dealing neither with solid liquid nor gaseous particles but with matter in a fourth state—radiant matter he called it then—which Sir Oliver Lodge described as something much smaller than *the atom fragments of matter* ultra atomic corpuscles minute things very much smaller very much lighter than atoms things which appeared to be the foundation stones of which atoms are composed Johnstone Stoney nearly twenty years later showed that a definite charge of electricity was associated with the ions of matter and this charge he called an electron It was later still that electrons were found to be the same as radiant matter capable of existing independently The identity of matter with electrons threw all our notions of what constitutes a chemical element into temporary confusion Chemists began to ask themselves What is the actual ultimate element? The very idea of an element as something absolutely primary and ultimate was growing less and less distinct until to-day we admitted the possibility of resolving the chemical elements into simple forms of matter or even of refining them away altogether In 1886 he ventured to revive the speculation that behind and anterior to matter was a substance (sub stans) which he called protyle By the operation of forms of energy on protyle he drew a picture of the gradual formation of the chemical elements, those of lower atomic weight *forming first then those of intermediate weight*, and finally the elements of highest atomic weight, such as uranium What comes after uranium? he asked, and he answered back The result of the next step will be the formation of bodies the dissociation of which *is not beyond the powers of our terrestrial* resources This was little more than a dream twenty five years ago but a dream which daily drew nearer to entire and vivid fulfillment Now in the twentieth century, ideas were floated which lead us *to think the old views of Empedocles might not be* so hopelessly absurd as they were considered some years ago Regarded as elementary attributes all Nature was included in the ideas of earth water air and fire The conception of solidity was embodied in the word earth water stood for the state of liquidity air represented the gaseous condition while fire stood for all forms of preponderable energy Opinions differed as to the constitution of the electron Some consider it to be an electrical charge on a material substratum others saw no necessity for the material nucleus and considered the electron to be pure disembodied electricity, thus approaching to the old idea of Buscovitch accepted by Faraday that the atom was only a center of force

But if we were dubious as to the constitution of the electron, physicists had settled many of its physical constants Taking as a standard the atom of hydrogen the smallest material body hitherto recognized the mass of the electron was 1/7000 of an atom of hydrogen and it moved with a velocity of two-thirds that of light It was easy to see that its kinetic energy was enormous equal to 3,500 000 foot tons per milligram So far he had given speculations with no apparent connection Chemists had been battering at the door of the unknown doing their utmost to get a glimpse of a few of the secrets so darkly hidden Suddenly an unexpected, almost incredible thing happened radium the epoch maker was discovered and then speculations which were drifting in chaos began to show some signs of order Radium, judged by severest chemical canons had all the attributes of a chemical element. *It formed salts* with the halogens it had a definite atomic weight it had a well-defined characteristic spectrum and it had the appearance and luster of a metal A bit of radium that would go into a thimble had almost shaken our belief in the conservation of substance the stability of the chemical elements the undulatory theory of light and the nature of electricity Radiant matter and radium had given us a new science—that of radio-activity Not only had radio-activity revealed to us the fact that the element radium was changing into helium but chemists alert to the strange metamorphosis had traced similar changes in other directions Derived elements were revealing themselves with bewildering rapidity more than twenty being known—and the cry was 'still they come

It was in the ores of uranium that radium was first discovered, and for some time they were considered to be only accidental associates later work had shown them to be interchangeable Uranium itself was undergoing slow change, passing through one or more intermediate forms into radium He likened uranium and the new bodies proceeding therefrom to a genealogical tree There were more than twenty of these new bodies, all of which deserved the appellation of elements But whereas the elements of the nineteenth century were apparently everlasting, these upstart elements had finite existences Uranium for instance has a life duration of 300 000,000 years, radium one of a few thousand years others of a few days, and so on till we came to those whose life history was rounded by four seconds Nature supplies us with facts which were riddles until the law of change was recognised. One body in its mineral ore was almost always associated with another body, sometimes in small, and at other times in larger, quantities Let no one however, contemplate wealth beyond the dreams of avarice by laying down a cellar full of lead and waiting for it to mature into silver and gold Probably the expected transmutation would occur, but its completion would require a lapse of time compared to which the 300 000 000 years' life of uranium would be a trifle

Physicists were now beginning to say that there was no such thing as matter, that when we had caught and tamed the elusive atom and split it into 700 little bits, these residual little particles would turn out to be nothing more than superposed layers of positive and negative electricity He refrained from speculating as to what would happen if some clever researcher of the future discovered a method of making these alternate layers of plus and minus cancel each other out!

It must never be forgotten that theories were more than mutable they were only useful so long as they admitted of the harmonious correlation of facts into a reasonable system Directly a fact refused to be pigeon holed and would not be explained on theoretic grounds the theory must go or it must be revised to admit the new fact The nineteenth century saw the birth of new views of atoms electricity, and ether Our twentieth century views of the constitution of matter might appear satisfactory to us, but how would it be at the close of the present century? Were we not incessantly learning the lesson that our researches had only a provisional value A hundred years hence should we acquiesce in the resolution of the material universe into a swarm of rushing electrons? He could not conclude better than by quoting some words he wrote more than thirty years ago We have actually touched the borderland where matter and energy seem to merge into one another—the shadowy realm between the known and the unknown I venture to think that the greatest scientific problems of the future will find their solution in this borderland and even beyond Here it seems to me lie ultimate realities, subtle, far reaching wonderful '

Real Wild Horses

It was the Russian explorer Prjevalsky who discovered a new and quite distinct wild horse in the Gobi Desert to the south of Mongolia. Although evidence existed that wild horses were probably as abundant in prehistoric times in the south of Europe as zebras are to day in British East Africa most naturalists believed that true wild horses with an unbroken line of wild ancestry were extinct. Hence great interest was felt in Prjevalsky's discovery Later the brothers Grum Grjimailo saw the horses in the desert and learned new facts about them

The Russians decided to capture a number of the animals and take them to Europe Their efforts were successful and several years ago a herd of about thirty of the Prjevalsky horses after much trouble were landed in Europe Most of them are still in Russia, but a few were taken to England where they are kept on the estate of the Duke of Bedford

The English naturalists did not make a scientific study of the animals in that country because the Russians have had a most thorough investigation in progress, with the advantage that nearly all the captive horses and a number of skeletons are in their hands. Very few of the English naturalists believed that they were true wild horses but looked upon them either as a kiang hybrid—the kiang being a species of ass—or as the offspring of escaped Mongol ponies.

The Russians, however, appeared to have settled the question They have proved it is claimed, by the methods of comparative anatomy and in other ways that the Prjevalsky horse has no relationship with Mongol species or the kiang but is a valid and distinct species of the genus horse without relationship to the ass although it has some features that remind one of the Asiatic ass, but even in these features, as the tail for example, the resemblance is closer to the horse than to the ass

The animals were mere colts when they arrived in Europe, and were not prepossessing, for they did not take kindly to the novel surroundings, were out of condition and had ragged coats and awkward gaits They have now reached maturity, have been well cared for and are good-looking animals.

Many naturalists hold the opinion that the domestic horse of to-day was mainly derived from three wild species, which have been named the steppe, forest and plateau varieties The Prjevalsky horse is a representative of the steppe variety

The brothers Grum-Grjimailo, who have had the best opportunity to observe this horse in its wild state say that it lives in the level districts and goes at night to the pasture-lands and drinking-places. At break of day it returns to the desert, where it rests until sunset

When there are nursing colts in the herd the animals always rest in the same place, but this does not appear to be the case when the foals become larger.

They usually walk one behind the other, so that the region where they live is [illegible]

They neigh clearly and the sound is exactly like the neigh of the domestic horse There is the same resemblance between the snorting of a badly frightened wild horse and that of domestic horses when scared.

The Mongolians have made many attempts to tame the wild horses, but in vain All efforts to tame the animals that have been taken to Europe have also failed Thus far the horse will not submit to man, is afraid of him, and cannot be rendered serviceable. Although now accustomed to the sight of human beings, the captives are very badly frightened if a person approaches nearer than two or three rods of them.

Recently the use of iron wire instead of platinum in the manufacture of electric light bulbs was forecasted by Dr. H. J. S. Sand, of the Nottingham University College. Dr Sand gave a demonstration of vacuum-tight seals between iron and glass. He announced his discovery of a method of sealing iron wire vacuum-tight in glass. Till now, he said, the only metal [illegible]

The Number of Stars in the Universe

How Celestial Bodies Are Counted

By Otto Hoffmann

One of my favorite books is Prof Newcomb's little volume entitled "The Stars," from which I have often derived both instruction and inspiration When this book was published a few years ago, certain views expressed in it created a mild sensation These views, according to which the stellar universe is limited in space and composed of a finite number of stars have since crystallized into a theory of great probability

It was always foolish indeed to assume the existence of an infinite number of stars The only ground for this assumption is the apparently infinite number of stars visible even with the naked eye Yet the number of such stars is surprisingly small The Almagest," attributed to Ptolemy which was really written by the Greek physician Hipparchus enumerates about 1 000 stars and approximately the same number is given in the catalogues compiled by the Arabian Al Sufi and by Ulugh Beigh a grandson of the famous conqueror Tamerlane These old catalogues however include only bright and conspicuous stars It is certain that a much larger number was visible to the ancient observers About 2 000 stars can be seen above the horizon at one time on a clear night by the average eye. According to Backhouse more than 25 000 stars would be visible to the naked eye if there were no atmosphere. The German astronomer Heis who possessed uncommonly keen sight published in 1872 an atlas which contained 4 943 stars visible between the north pole of the heavens and the 20th degree of south latitude This work was supplemented in 1874 by Behrmann's atlas containing 2 306 southern stars The sum of these two numbers 7 249 represents the whole number of stars that can be seen by unusually good eyes.

The number of stars revealed by the telescope is enormously greater than this The most extensive star catalogue which we possess is the work of the indefatigable Argelander of Bonn who in the middle of the 19th century indicated the places of all known stars down to magnitude 9 5 situated between the north pole and the second degree of south latitude 324 189 stars in all Argelander's work has been extended southward by his successors Schoenfeld at Bonn and by Gould and Thome at Cordoba, Argentina and is not yet quite finished The complete catalogue will give the places of about 800 000 stars as stars of the 10th magnitude are included in the Cordoba observations

All of these numbers however are very much smaller than the total number of stars actually in existence Sir John Herschel estimated that 5½ million stars could be seen with his 20-foot telescope Struve estimated the whole number of stars at 20 million Pickering thinks that more than 50 million stars can be seen with the great refracting telescope of the Lick Observatory, which shows stars of the 16th magnitude

Still fainter stars can be photographed with long exposures Dr Roberts's photographs of the sky show about 64 million stars according to Core's estimate The Carte du Ciel, the international photographic atlas of the heavens the production of which was decided upon at a congress which met in Paris in 1900 is expected to show 13 million stars although it will not include any stars smaller than the 14th magnitude The whole number of stars in our stellar system is several hundred millions according to Newcomb and a thousand millions according to Dyson

That the stars cannot be infinite in number is evident from the following considerations The fainter stars taken together emit more light than the brighter stars Hence if the number of stars were infinitely great the whole sky would appear as bright as the noonday sun In reality the background of the sky is quite dark and the total amount of light which we receive from the stars is very much smaller than that which the sun sends to the earth Prof Newcomb concluded in 1901 that the total starlight is only 728 times the light received from the star Capella or 1/89 the light of the full moon

These statements will be made more intelligible by an inspection of the following table containing the number of stars of each stellar magnitude

Magnitude	Number of stars
Between 1st and 2nd	19
Between 2nd and 3rd	105
Between 3rd and 4th	300
Between 4th and 5th	1 016
Between 5th and 6th	3 265
Between 6th and 7th	10 200
Between 7th and 8th	31 000
Between 8th and 9th	93 000
Between 9th and 10th	271 000
Between 10th and 11th	710 000

This table shows that the number of stars of each magnitude is about three times that of the preceding magnitude By continuing to apply this ratio we obtain more than 1 500 million stars between the 17th and 18th magnitudes But the light of a star of a given magnitude is not 3 times but only 2½ times greater than that of a star of the next following magnitude Hence the light received from all stars of the 9th magnitude for example is considerably greater than the light received from all stars of the 8th magnitude If the universe contained an infinite number of stars distributed among smaller magnitudes even approximately according to these laws the amount of light and of heat received from all the stars would evidently be infinitely great or at least insupportable

Struve impressed by this difficulty many years ago assumed that the light of the stars is weakened by absorption in interstellar space The value which Struve assigned to this absorption must be regarded as arbitrary and for a long time it was impossible to decide whether any such absorption occurs The recent researches of Kapteyn Nordmann and Tikhoff prove that starlight is slightly absorbed in its flight through space but the amount appears far too small to create a new basis for the assumption that the number of stars is infinitely great – Prometheus

New Discoveries at Knossos

The Remarkable Revelations of Dr Evans

By H R Hall

A LETTER has recently appeared from Dr Arthur Evans describing the results of his excavation this year at Knossos There were many more things that we wanted to know about Knossos and one of them has been made clear by the work of this season The great domed pit the *tholos* as it seemed to be over which part of the southern quarter of the palace was built, has been excavated to the bottom not without danger to the workmen And it turns out to be a great *tholos* like reservoir with a spiral staircase round the inside of it which breaks off as in other similar cases at what must have been the average water level The springs that supplied this reservoir are now dry and no doubt were so before the place was entirely filled up This was done as we know from the character of the potsherds found in it, in the first Middle Minoan age

"In other words the reservoir itself belonged to the Early Minoan Age and was filled in at the time of the construction of the first palace of which we have any existing remains—the object of the work being to obtain a secure foundation for the South Porch and adjoining parts of the outer wall The filling materials themselves were probably supplied by the leveling away at this time of the summit of the Tell of Knossos in order to gain the area for the central court of the palace." There was also a smaller reservoir on another part of the mound "and from the magnitude of the work we may well conclude that some earlier predecessor of the great palace already existed on the site that it has since occupied

This is an important conclusion. If we are to judge by the reservoir, the early Minoan palace was probably a great architectural work The Early Minoan III architects were perhaps almost as capable as their contemporaries, the Egyptian pyramid-builders of the fifth and sixth dynasties.

[illegible] small "palace" on the hillside west of [illegible] further discoveries have been made, including [illegible] way with the rut-marks of ancient [illegible] In this part of the site more recent remains of classical and Roman date constantly are found above the Minoan level whereas in the main palace whether owing to a superstitious awe or to other causes the hilltop was never invaded by later habitations A fine metope of a Doric temple contemporary with the Parthenon sculptures was found over the western palace

Mr Doll has proceeded with the work of conserving the palace buildings and has run the great staircase another flight higher Also the nature and composition of the frescoes have been studied by Mr Noel Heaton

In the tomb-field of Isopata further important discoveries have been made owing to the *flair* of Gregori Dr Evans's Cypriote foreman 'the most expert tomb-hunter of the Levant. The wild long rooted fennel which seeks out by preference the spots above ancient cuttings served him as often before as a guide and the result was the discovery of six chamber tombs some of which for their size and the interest attaching to their contents and arrangement surpass any hitherto known of this class

The date of the tombs is the second late Minoan period about 1450 B C contemporary with the eighteenth dynasty of Egypt. The most remarkable point about these tombs is the information as to Minoan religion which they give us In one tomb where the religious interest culminated was found an arrangement wholly new which rather recalled the domestic Etruscan ideas of the after life than anything yet known of the Minoan age The tomb was made to resemble a house of the living with stone-cut benches as if for family gatherings And at the head of the sepulchral cist were found the remains of a double-ax shrine with an offering vessel, in the shape of a bull's head lying close by These tomb-chambers seem not to have been kept open regularly but were opened for solemn service on the anniversary of the death probably They were rifled of their more valuable contents by robbers of the early Iron Age (geometrical period), who left behind traces by which we can identify their date

It will be seen that the Tomb of the Double Axes has produced more definite evidence regarding the sepulchral cult and religious ideas as to the after world than any grave yet opened in Crete or prehistoric Greece

Dr Evans's comparison of the interior of the tomb with that of an Etruscan grave is very apposite and suggestive This Etruscan impression has already been given by the great painted sarcophagus found by the Italians at Agia Triada and it is most interesting to see how a relationship between the Etruscan Minoan and Anatolian (Hittite) cultures in matters of religious cult is gradually becoming clearer to us —Nature

Waterproof wall paintings on a finished back ground of mortar made from lime quartz sand in fusorial earth and water are prepared as follows Painting ground Four parts of quartz sand 3 5 parts marble sand 0 5 part infusorial earth heated to redness 1 5 parts thick lime paste After drying the painting ground is to be coated with hydrofluosilicic acid and impregnated several times with potash water glass earth colors which have been digested for a long time with potash water glass are used After dilution the silicic acid is separated by means of carbonate of ammonia from the water glass which remains in intimate combination with the colors To the washed-out colors hydrate of alumina and hydrate of magnesia are added they are rubbed down and preserved in paste like condition The pictures are fixed by means of a spraying apparatus and a fluid obtained by heating 200 parts of potash water glass 100 parts caustic ammonia, 10 parts caustic potash and 12 parts marble powder and decanting this from the residue After fixation which must be done four to five times at a temperature of 100 deg to 120 deg F, the painting must be washed with carbonate of ammonia, then with water, and finally impregnated with a solution of paraffine in petroleum ether

Automatic Stabilizing System of the Wright Brothers

An Interesting Control System Devised by the American Inventors

IT IS well known that the control of the Wright aeroplane makes great demands on the attentiveness and skill of the pilot and that long practice is required in order to learn the art of steering. The steering of a Farman, Sommer or Voisin biplane can certainly be mastered in a shorter time and this may be the reason why more pilots are to be found for machines of these types. In order to facilitate the guiding of their biplane the Wright brothers have devised an automatic stabilizing system. The following description of this system is derived from the British patent 2,913 of the year 1909 and the French patent 401,905.

A flying machine is in equilibrium when the resultant of all air pressures is vertical and passes through the center of gravity. The position of this resultant, however, is dependent upon the angle which the sustaining planes make with the apparent direction of the air current which is in general opposite to

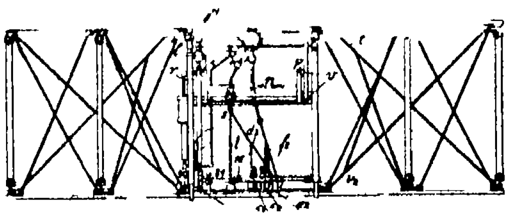

Fig 1 —Front elevation of the Wright biplane with automatic stabilizing system

the direction of flight. Any change in this angle alters both the magnitude of the resultant force and its position relatively to the center of gravity. These changes in the resultant affect the angle of incidence in turn and so the disturbing factors rapidly augment each other and the machine soon capsizes unless the disturbance is checked at its first manifestation by proper manipulation of the elevating and steering rudders and by warping the sustaining planes.

Two devices almost identical in principle and in construction have been adopted by the Wrights for the purpose of assuring an immediate and automatic restoration of the angle of incidence to the value which held the aeroplane in equilibrium on its definite course before the disturbance occurred. In one of these devices the elevating rudder is operated by an auxiliary plane whenever the aeroplane pitches or turns about its transverse horizontal axis, while the other device, which includes a pendulum, operates the vertical rudder and warps the sustaining planes whenever the machine rolls or turns about its longitudinal horizontal axis. No special mechanism is provided or required for insuring stability with respect to the vertical axis because the torque about this axis which is produced by the warping of the sustaining planes is compensated by the association of lateral steering with the warping. Zigzag flight, if it is not entirely prevented by the vertical stabilizing planes of the newer Wright biplanes, can easily be checked by hand steering before it becomes a source of danger.

The mechanism employed for the prevention of pitching is connected with the horizontal or elevating

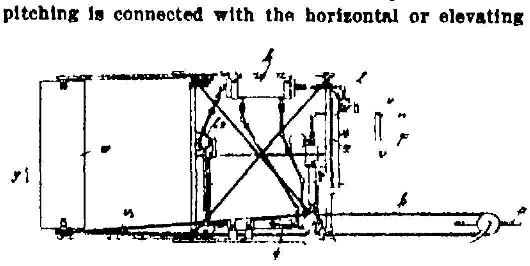

Fig 2 —Side elevation of Wright biplane with stabilizing system

rudder. This rudder a (Fig 2) is placed in front of the sustaining planes and a grooved wheel on its shaft is connected by a cord b with another grooved wheel c_1 (Fig 3) which can be turned by the hand lever d^1. The shaft of the wheel c^1 carries a loose wheel c which can be disconnected from c_1 by pressing the spring f^1. When the two wheels are connected the rudder is operated automatically by means of the mechanism now to be described. The wheel c is connected permanently by the rod g with the differential piston shown in Fig 4. The lower cylinder i in which the small head of this piston moves communicates permanently with a reservoir of compressed air by means of the inlet j so that the piston is always subjected to pressure from below. The upper and larger cylinder h can be put in communication with the reservoir by means of the inlet j_1 and the three-way cock shown in Fig. 5, which can also be adjusted to put the cylinder h in communication with the atmosphere or to isolate it completely and thus to stop the piston. These connections are made possible by the arrangement of the channels of the three-

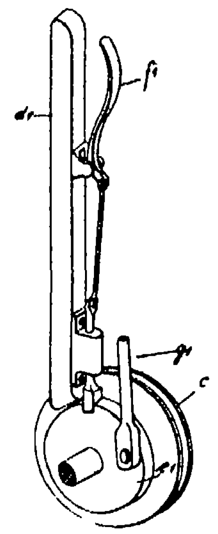

Fig 3 —Handle of elevating rudder

way cock as will appear on inspection of Fig 5. The three-way cock is turned by the movements of an auxiliary plane, the arrangement and the operation of which are illustrated by Fig 6. The auxiliary plane n is attached to the vertical arm p. The ends of this arm are connected by hinges to the outer ends of two equal and parallel arms vv whose inner ends are similarly connected to the rod r. The weight of the plane and the arms is balanced by a counterpoise attached to an extension of the lower arm v. The vertical movement of the plane is limited by the stops q. When the plane is depressed to its lowest position, indicated by the dotted lines in Fig 6, by air pressure from above, it turns the three-way cock l into such a position that the large differential cylinder h is put in communication with the outer air through the channels m and m_1 (Fig 5). The piston (Fig 4) is consequently forced upward by the excess of pressure in the lower cylinder i (which communicates permanently with the compressed air reservoir). As the piston rises it draws upward the connecting rod g (Fig 3) and thus turns the wheels c and c and by means of the cord p (Fig 2) gives the elevating rudder a an inclination which causes it to lift the bow

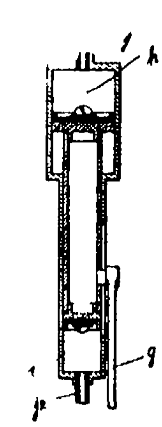

Fig 4 —Differential cylinder

of the aeroplane. The opposite effect, depression of the bow, is produced automatically whenever the auxiliary plane n (Fig 6) is forced upward by air pressure from beneath so that it turns the three-way cock to a position in which the tubes j and j_1, leading respectively to the compressed air reservoir and to the upper differential cylinder, are connected by means of the channels m_1 and m_2 (Fig 5). The piston is then forced down in consequence of the inequality in area of its two heads.

Let us now see in what conditions the auxiliary plane is impelled to produce these results. The auxiliary plane is inclined to the principal sustaining planes at an angle which the inventors call the critical angle of incidence and which is equal to the angle between the sustaining planes and the apparent air current or relative direction of motion. Hence, when the aeroplane is moving forward without disturbance the relative air current is parallel to the auxiliary plane, which consequently remains at rest in its neutral or middle position. If, however, the inclination between the sustaining planes and the relative air current becomes less than the critical angle, and the machine tends to fall in consequence of the diminution of the vertical component of the air resistance, the auxiliary plane is forced down causing the differential piston to rise and turn the elevating rudder upward. If the three-way cock and the arms which carry the auxiliary plane were attached directly to the frame of the machine the critical angle of incidence would be invariable and an arbitrary and a uniform elevation or depression would be produced by the device. The arms and the three-way cock, however, are attached to the rod r (Fig 6) which is suspended from the frame by a hinge at s. The magnitude of the critical angle is determined by the position of this rod relatively to the frame and sustaining planes, and this position can be varied by means of an adjustable clamp at y. In ascending, for example, the rod r is swung backward in accordance with the increased

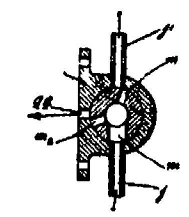

Fig 5 —Three way cock

angle at which the relative air current strikes the sustaining planes and the angle of ascent is maintained constant by the automatic operation of the auxiliary plane and its accessories as long as the rod r remains clamped in this position. The practical efficiency of the device, especially in variable winds, can be demonstrated only by experiments of which no account has yet been published to the writer's knowledge. The inventors admit that the disturbing influences are not exactly compensated but that the auxiliary plane and the elevating rudder are first moved too far and oscillate before they settle down into their new positions. In the writer's opinion periodical gusts of wind might do more damage with this device than without it.

A simpler form of the apparatus is shown in Fig 7. Here the auxiliary plane n is attached directly by a hinge to the frame of the machine while an additional positive or negative angular displacement can be given to the three-way cock l, by means of the lever r.

The apparatus employed by the Wright brothers for the purpose of assuring stability with respect to the longitudinal axis is very similar to the device described above. It includes a differential cylinder with its smaller chamber in permanent communication with the compressed air reservoir, with which the

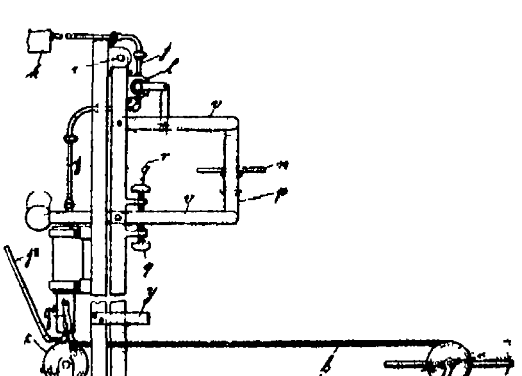

Fig 6 —Side elevation of fore and aft stabilizing mechanism with auxiliary plane

larger chamber can be connected by means of a three-way cock. Here, however, the three-way cock l_2 (Fig 8) is operated by a pendulum t. The manner in which the warping of the sustaining planes and the turning of the vertical rudder are automatically produced is illustrated by Figs 9 and 10. The hand steering lever d_2 (Fig 9) is attached to a grooved wheel c_2 mounted on the lower sustaining plane to the left of the pilot, which is connected with the loose wheel c^2 except when the bolt w (Fig. 10) is drawn back by pressing the spring f_2. The loose wheel c_2 is permanently connected by the rod g_2 with the differential piston, while the grooved wheel c_2 is connected by the cord v_1 with the warping cord v_2, which runs to the tips of the sustaining planes. The vertical rudder x is connected by the cord v_3 with another grooved wheel c_3, which can be connected with the shaft by the friction clutch u and which is also provided with a hand lever d_3.

If the aeroplane rolls so as to raise one end of the sustaining planes, as in Fig 8, the pendulum t swings to the opposite side and turns the three-way cock l_1 so as to produce an excess of pressure in one chamber of the differential cylinder, causing the piston and its connecting rod g_1 to move either forward or backward The result is that the warping cord v_2 is pulled to right or to left by the cord v_1, twisting the tips of the sustaining planes, and that the vertical rudder is simultaneously turned by the cord v_3 to an extent sufficient to counterbalance the horizontal torque produced by the warping of the planes In this case

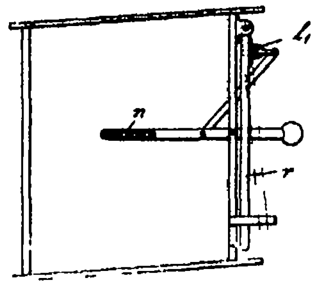

Fig 7 Simplified arrangement of auxiliary plane

also the disturbing influence is not counteracted exactly and instantaneously but the pendulum and the rudder perform a number of oscillations before they come to rest in their positions of equilibrium

In beginning a curved flight the friction clutch is loosened and the rudder is turned by hand independently of the warping of the planes If the friction clutch is then tightened with the rudder in an inclined position the machine will continue to fly in a curve and the automatic mechanism will act as efficiently as it does in pursuing a straight course

It has already been remarked that no experiments made with these stabilizing devices appear to have been published Is this because the Wrights are overwhelmed with orders or because the expectations founded on these devices have been disappointed? If the devices had proved their practical efficiency it would certainly be to the interest of the Wrights to exploit an invention which was announced in the United States in the beginning of the year 1908

In the writer s opinion the influence of the pendulum must be eliminated in curved flight as otherwise the warping effected by hand which depresses the side nearest the center of curvature of the path would be counterbalanced by the action of the pendulum swinging outward in obedience to centrifugal force The loosening of the friction clutch at a moment when the attention of the pilot is fully occupied is a serious defect of the pendulum apparatus

The Manufacture of Hydrogen

There has been a large increase in the manufacture of hydrogen within recent years due principally to three causes—(1) the construction of dirigible balloons (2) its use in the manufacture of tungsten filaments for electric lamps and (3) the oxyhydrogen blow pipe flame The demand for the gas in connection with dirigible airships and the manufacture of lamp filaments seems likely to increase very largely in the near future and it is therefore opportune at the

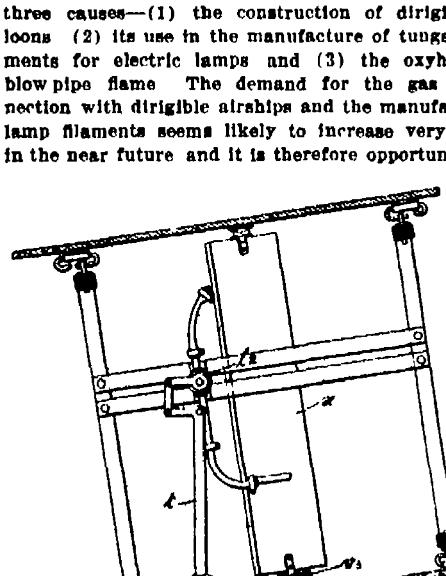

Fig 8.—Front elevation of transverse stabilizing mechanism with pendulum

present time to examine the present sources of supply and the methods of manufacture employed

Hydrogen, which is about 14 39 times as light as atmospheric air, has a much greater lifting power for aeronautical purposes than coal gas, although in point of cost the latter compares favorably The chief drawback of the use of hydrogen for inflating balloons is its high rate of diffusion, which is 3.88 if the rate of diffusion of air be taken as unity. Although this drawback is being minimized by improvements in the [illegible] fabrics, it is highly important for the maintenance of large dirigible balloons to be assured of a regular supply of pure hydrogen gas

The manufacturer of tungsten filaments for metallic filament lamps requires a regular supply of hydrogen to prepare the inert atmosphere in which the filaments are heated to a high temperature during the final treatment There is some doubt whether the hydrogen is really inert in this operation and in those cases where a carbonaceous binding material is employed the hydrogen probably assists in the complete removal of the carbon it having been shown that carbon unites slowly with hydrogen to form methane at a temperature of about 1 000 deg C (1 832 deg F) However this may be it is the almost universal custom to employ a mixture containing approximately equal proportions of hydrogen and of nitrogen when the filaments are heated to a white heat by the passage through them of an electric current during the sintering operation Since tungsten filaments when heated to incandescence are extremely sensitive to oxidation it is of great importance that the hydrogen employed should be of a high degree of purity

For the autogenous welding of metals the working of platinum and the manufacture of laboratory utensils and mercury vapor lamps from fused quartz hydrogen in the form of the oxyhydrogen blow pipe flame is used in large quantities although here it has to meet the competition of acetylene a gas which is cheaper and readily obtainable as required from calcium carbide

The preparation of hydrogen by the action of dilute sulphuric acid upon metallic zinc like most of the other methods usually employed in the laboratory for

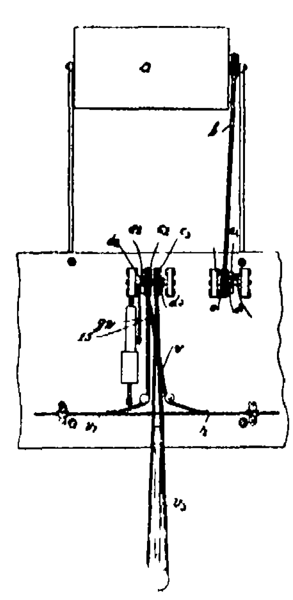

Fig 9—Plan showing elevating rudder and its connections above and vertical rudder and its connections below

this purpose is too costly to be capable of being carried out on a large scale

During the Russo-Japanese war the balloon corps of the Russian army are stated to have been equipped with a portable hydrogen plant consisting of generators in which the gas was produced by the action of a concentrated solution of caustic soda upon aluminium shavings This method has the advantage of readily yielding a plentiful supply of hydrogen in a state of high purity from apparatus and materials of small bulk but it is much too expensive to be capable of extensive application Experiments have been made at Bitterfeld in Germany with a compound calcium hydride prepared by passing hydrogen gas into molten calcium metal This substance is very similar in its behavior to calcium carbide and on treatment with water spontaneously gives off hydrogen in the same way as the carbide yields acetylene Little is known concerning its cost of production but if it could be produced on a commercial basis it would obviously possess great advantages as it would overcome the necessity of transporting the gas in compressed form in steel cylinders Frank of Berlin has patented a method of producing hydrogen by passing water gas over heated calcium carbide This absorbs nitrogen at a temperature of 300 deg C (572 deg F) and by removing oxides of carbon with suitable reagents hydrogen gas suitable for inflating balloons can be obtained

These processes are interesting from a theoretical point of view and are merely instances of the large amount of experimental work which has been carried out with a view to providing hydrogen for commercial use on a large scale At the present time most of the hydrogen used for inflating the gas bags of dirigible airships is produced either electrolytically or by the action of steam on red hot iron turnings

The electrolytic process has been developed to a considerable extent in Germany and is an application on a large scale of the well known decomposition of water into hydrogen and oxygen by means of an electric current It depends for its success upon a cheap supply of electric energy and as for every two volumes of hydrogen there is simultaneously produced one volume of oxygen this is also a source of profit The plant requires comparatively little attention and the hydrogen may be generated in a condition of great purity

The other method has been developed in this country by Howard Lane In this process steam is passed over red hot iron whereby hydrogen is produced and the metal converted into oxide The oxide formed however can be reduced again to metallic iron by passing water gas coal gas and other gaseous fuel into the

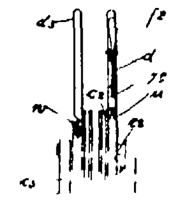

Fig 10—Wheels and levers for controlling vertical rudder and warping sustaining planes

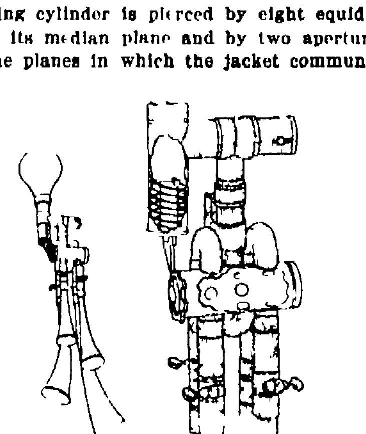
retorts By employing a number of retorts some of which are producing hydrogen while in others the oxide is being reduced it is possible to arrange for a more or less continuous supply of gas Lane s process has found favor with manufacturers of tungsten lamps because it is also possible to arrange the plant so that when the oxide is being revivified nitrogen can be collected it being customary for the lamp filament makers to employ a mixture of hydrogen and of nitrogen

The various methods of producing hydrogen on a large scale have occupied the attention of the war departments of several governments as well as that of the aeronautical societies and the great progress which is now being made with dirigibles is bound to act as a stimulus to greater activity among chemists and engineers engaged on this problem There is undoubtedly much to be done before aeronauts can be sure of the immediate delivery of hydrogen in sufficient quantities to meet their requirements—London Times

The Testophone

The testophone is a new automobile horn so contrived that the monotonous repetition of the same sound is avoided A blast of air forced into a pump barrel by compressing an India rubber bulb moves a piston the rod of which carries a pawl that engages with a ratchet wheel of eight teeth attached to the end of a horizontal cylinder which is capable of rotation inside a fixed cylindrical jacket The cylinder is thus turned through one-eighth of a revolution each time the bulb is compressed An air pipe connects the middle of the pump barrel with the middle of the jacket of the rotating cylinder and the jacket communicates also with four horns of different pitches by means of four outlets distributed above and below its axis and to the right and left of its median plane The rotating cylinder is pierced by eight equidistant orifices in its median plane and by two apertures in each of the planes in which the jacket communicates



THE TESTOPHONE

with the horns As the cylinder rotates its eight median apertures are brought successively opposite the air inlet of the jacket and it is put into communication successively with the horns by means of its lateral openings which are so arranged that no two horns are sounded simultaneously, and each horn is sounded twice in the course of a complete revolution—La Nature

Drawing Points of Waxed Charcoal—Well burned lime tree wood charcoal is cut into the form of the ordinary sticks which must be laid in melted wax and left there about 15 to 20 minutes Take them out, dry them between blotting paper remove adhering wax and rub them off with flannel rags

Disposition of Garbage in Various Cities

The Installations of Some European Communities

HAMBURG *

In the northern and northwestern sections of the city of Hamburg garbage and house refuse are collected and carted to districts beyond the city boundaries to be spread over fields and eventually to be plowed under as fertilizing material In the central eastern and southern boroughs including the harbor such material after being collected is incinerated in a municipal establishment commonly regarded as a model of its kind and one which has given perfect satisfaction during the entire fourteen years of its practical use I am convinced that American municipalities can study profitably the experience of Hamburg in this very important matter

The refuse reduced to ashes in the municipal plant is conveyed thither in 4 wheeled water tight iron carts each of which has a capacity of about 4 cubic meters (141 cubic feet) The cart bodies can be lifted from the wheels by means of electrical traveling cranes and the contents discharged directly into the furnace There are 36 of these furnaces built according to the method of a firm in Leeds England all of which burn continuously except when they require cleaning When the fires are once started no commercial fuel is required and therefore the consumption of coal in the plant is insignificant

The slag is removed from the furnaces in small iron carts and conveyed therein to a cooling apparatus where the contents are sprinkled with cold water and then to the slag breakers which are capable of producing broken slag in three sizes in the following proportions 16 per cent passing through a 5 millimeter mesh screen (0 197 inch) 50 per cent passing through a 2 millimeter (1 inch) mesh screen 34 per cent passing through a 60 millimeter (2 36 inch) mesh screen An electric magnet is in operation in connection with the slag breakers and it removes small pieces of iron the larger pieces having been removed from the refuse before passing into the furnaces or if such are contained in the slag they are thrown out of the rotary sieve drum at the lower end of the breaker

The scrap iron recovered is sold at public auction and the slag itself is disposed of at a fixed price of 23 8 cents per ton of 1 000 kilos (2 204 6 pounds) There is always a great demand for this slag for which there are numerous applications The fine cinders are used as a top dressing for promenades the coarser grade for establishing the drainage foundation of roads and the middle size for the top dressing of roads Used in this way garbage slag is cheaper than any substitute material and it serves its purpose perfectly It is used advantageously in mixing concrete 5 parts of coarse slag 1 part of cement and 3 parts of sand being the ordinary proportions or 1 part of cement and 7 parts of middle sized slag

The very fine garbage slag may be utilized wherever coarse sand can be used for example to form a bed for street paving blocks for the manufacture of slag bricks as antislipping material on city streets in winter and as filling material in buildings under floors and over ceilings Many other uses could be named

As a filling material between floors and ceilings this slag is used very extensively in docks and warehouses of Hamburg for the particular reason that it is absolutely sterile and unlike other kinds of slag contains no sulphur by which merchandise in storage is sometimes damaged

The garbage incinerating furnaces furnish sufficient power to drive all the electrical machinery in the establishment to operate the cranes slag breakers and light plant furnishing also electricity for the accumulators of an electric motor launch and an electric motor cart used in the transportation of garbage At present only one motor cart is in use and it is proposed to purchase a number of others so that within a few years horses will be eliminated entirely in the handling of garbage

Such city garbage as is not burned is utilized frequently to fill up marshes and swamps as well as for fertilizing purposes

Contracts for the removal of garbage whether for destruction by fire or for other disposition are awarded by the government to private firms upon public tenders and in several lots described according to the distances to be covered in transporting the refuse Two firms for years have secured such contracts These own the necessary horses and stables and rolling stock and furnish the men the carts in which refuse is conveyed to the incinerating plant are municipal property placed at the disposition of the contractors Having very considerable outfits, the two firms seem also to control the transportation of sand gravel, paving stones, and bricks within the city

The present contracts for the removal of garbage were made in 1905 for a period of five years The city pays $107 to $132 according to distance, per 1 000 inhabitants served (The city of Hamburg has a population of 895 804) New contracts were made this year with the same firms, according to which the contractors will receive $136 to $202 per 1,000 inhabitants but these contracts are to run for two years only, for the reason that a second incinerating plant is in the course of construction and will be ready for use within that time.

The new destruction plant is being arranged much like the old one except that the experience of fourteen years has been utilized and instead of Horsfall furnaces the so-called Hamburger Öfen will be employed The new ovens are not unlike the Horsfall ovens but are believed to have been improved upon to such an extent that whereas the Horsfall furnaces can dispose of only 9 tons of material per twenty four hours the new ovens will dispose of from 22 to 25 tons during the same period

Householders in Hamburg are required to provide themselves with metal receptacles, which they place upon the curb line usually twice a week between 8 and 9 o clock P M The garbage gatherers empty the cans into their carts between 9 P M and the early morning hours The cans themselves are very seldom stolen and it is possible and indeed quite common to purchase numbered cans from private firms which if stolen are replaced by the insuring firm

The conditions in Hamburg are such that ordinary householders reduce the amount of garbage to be carted away as much as possible by destroying in kitchen stoves everything that can be burned

LONDON *

Acting on the request of American firms special inquiries were directed to the engineers of several of the boroughs of metropolitan London for securing information regarding the collection and disposal of garbage The substance of these replies is as follows

In the borough of St Pancras the collection of all garbage is supervised by officers in the direct employ of the borough council The collection of house refuse is carried on by a staff in the direct employ of the local authority The collection of street refuse is also made by the council s own staff but its removal from the streets is effected by contractors In the letting of contracts no distinction is made between individuals and corporations

The borough is divided into eight wards for which separate bids are received though sometimes more than one ward is given to a single contractor The contracts are for twelve months on a lump-sum basis —that is each bidder offers to remove the whole of the street refuse in any ward for a stated sum

For the removal of house refuse dust vans of 5 cubic yards capacity are employed two men accompanying each van Nearly all of the houses have portable dust bins which are carried out by these men and emptied into the van In a few cases there still remain fixed dust bins from which refuse has to be shoveled into baskets and carried to the dust van The collection generally proceeds all day from 7 A M to 5 P M but in certain main streets police regulations forbid dust vans to carry on their work after 10 A M and in these streets daily collection is made between 7 A M and 10 A M the residents being required to bring their dust receptacles to the footway

In the case of hospitals, large hotels and large restaurants daily collection is made and in some of the more densely occupied localities the collection is made three times or twice a week, but generally throughout the borough the collection of house refuse is made once a week No machinery is used in the disposal of the refuse The larger part is burned, while the remaining part is sent away by canal barges. The street refuse becomes the property of the contractors who remove it, and it is disposed of as they can best arrange It is nearly all sent away by barge on canal or river

In the borough of St Marylebone it has been the custom of the council to have house refuse collected and disposed of by contract. Bids are invited by public advertisement and the lowest bid is accepted, provided the council is fully satisfied, after inquiry, of the substantiality of the firm whose bid is proposed to be accepted The council accepts the bid for one, two, or three years, as it considers best. The cost of the work during the fiscal year ended March 31st, 1910, was $51,966.

Horse-drawn carts and vans are used for the collection of garbage, and the receptacles for carrying the refuse from the premises to the vans have to be approved by the medical officer of health. Strong wicker baskets or metal receptacles are used for this purpose The contractors collect the refuse during the whole of the day except in special streets, where the occupiers are required to place the refuse on the curb in proper receptacles before 9 A. M and the contractors are bound to remove it by 10 A. M

The refuse is taken away by barge on the canal, and while the paper and garbage is burnt the siftings of the refuse are used for brick making

In the borough of Islington the collection and disposal of garbage is undertaken by a department of the council s staff under the control of the borough engineer For this purpose the borough is divided into districts, each district, containing about 2 400 houses being served by a gang consisting of four dust loaders (one of whom acts as ganger"), three carmen, and three vans The several districts are divided into sections so that the houses of the several sections may be collected from on given days during the week and the occupiers are thus aware of the day of the week when the cart or van may be expected Householders as a rule are required to provide one or more movable receptacles constructed of metal of a capacity not exceeding two cubic feet each but sufficient to contain a week s accumulation of dust. The time of collection is from about 7 30 A M to about 5 30 P M, daily This system has been in force in this borough since 1895 and upon the testimony of the town clerk, is said to work very satisfactorily

The refuse from restaurants and eating houses if likely to become a nuisance when allowed to accumulate is collected two or three times weekly and in exceptional cases every day Trade refuse, which is defined in the public health (London) act of 1891 as meaning the refuse of any trade manufacture or business or of any building material ' is collected by special carts the charge being 2d (4 cents) per basket full

The refuse both house and trade, is carted to the council s depots adjoining certain railways passing through the borough and is tipped into railway trucks and conveyed to farmers and others along the line The council pays a small sum toward the cost of the railway rates The council has no dust destructors

In the borough of Paddington the garbage of about nine-tenths of the area is collected by the borough council and the remaining one-tenth by contractors. The contracts are let to individuals for a period of three years for a lump sum per annum The garbage is collected by horse-power covered tipping vans usually between the hours of 6 A M and 6 P M The garbage is removed by barge along the canal by the contractors The town clerk advises that machinery was abandoned several years ago

The by laws (ordinances) which govern the several borough councils are passed by the London county council a body which has jurisdiction throughout metropolitan London a copy of whose ordinances now in force for the public health is forwarded (and obtainable from the Bureau of Manufactures)

LIVERPOOL *

The work of collection and disposal of refuse in Liverpool is done entirely by the corporation of the city with direct employment of workmen and not by contract.

The total quantity of refuse collected per day in Liverpool is approximately 1 000 tons Combustible refuse is collected and destroyed at the corporation s destructors in the process of which steam is generated for various purposes The clinker residue from this operation is utilized for the manufacture of concrete slabs and making concrete for foundations, bricks, mortar etc The refuse collected from the streets of a manurial nature is graded and sold for agricultural purposes, according to the quality, In this material is included the refuse from fruit markets etc. Fish garbage is collected and disposed of for the manufacture of a patent fish manure. Old tins are separated and disposed of by being pressed by hydraulic machinery into billets and sold.

A separate class is made of waste paper, which is made up into bales and sold to paper manufacturers for repulp Oyster shells are collected, and after grinding utilized as poultry gravel, Incombustible material and garbage of no value is conveyed to sea by steam hopper barge and tipped in deep water

EDINBURGH.†

All refuse in Edinburgh is collected and disposed of by the municipal cleaning department. There is a daily removal system, the work of collection beginning every week day at 7 A. M A city ordinance provides that "any straw, chaff, ashes, dust, or house sweepings, or any offensive matter or thing" [illegible] be placed on a street or court [illegible] other [illegible] that [illegible]

* From Consul-General Robert P Skinner

* From Consul-General John L. Griffiths.

[illegible]

be placed on a street or court tied in a bundle, or after it has been reduced to pulp, and in the latter case the pulp must be contained in pails buckets, or other suitable vessels," that the time during which any of the above-specified material may be so placed on any street or court "shall be between 6 30 A. M on any lawful day and the time at which the collecting cart may on the same day, pass on its round, that vessels placed on a street or court must be removed therefrom within half an hour after their contents are emptied into the dust carts The penalty for each contravention of this ordinance is a fine not exceeding £5 ($24 33) or in default of payment imprisonment

All kinds of garbage ashes etc may be put out together in the same pail or box Street sweepings are collected separately from other refuse as is also stable manure

The number of workers in the cleaning department is 581 men and 54 boys who average about $6 10 and $3 per week of 52½ hours respectively A week s vacation in the year with full pay is allowed The total quantity of refuse (not including mud sand etc from macadamized roads) dealt with in the year ended May 15th 1909 (the latest period for which statistics are available) was 124 915 tons of which farmers took 21 631 tons (street sweepings and stable manure) and a destructor consumed 15 416 tons the bulk of garbage and other refuse being deposited near oil shale mines 7½ miles from the city limits to restore the level of the arable or pasture land

The destructor which takes the refuse from a small district is simply a furnace reducing everything to ashes or into the form of clinker this latter residuum being sold to builders and others in small quantities or when no demand exists dumped with the ashes into places in process of leveling up Into such places are also dumped all the mud sand etc from macadamized roads amounting annually to about 30 000 tons

The cleaning department received from farmers in the period mentioned $3 031 for street sweepings and $1 684 for stable manure delivered by rail On this material the railway freight alone was 16 cents per ton and on the refuse taken to the oil shale district the freight was 20 cents per ton At the destructor the disposal cost was 63 cents per ton Deducting revenues derived from the sale of manure clinker old tin cans etc and from special cleaning services at the city slaughterhouses and markets amounting in all to $16 997 the net cost of cleaning the streets and of collecting and disposing of refuse was $244 051 The average net disposal cost rate for refuse mud sand manure etc, taken together and totaling 184 930 tons was 22 cents per ton

There are some exhausted limestone quarries in the city s possession bought for the purpose of depositing garbage and other refuse on a tract of 115 acres called Burnhouse farm, 10½ miles from the municipal boundary I am informed by the chairman of the cleaning and lighting committee of the town council that in a short time the city will probably have these in use and it is thought they will prove to be the best and cheapest method of disposal

GLASGOW *

The collection and disposal of garbage is under the direct supervision of the superintendent of the cleansing department of the corporation The contract system, established in 1862 continued for six years when the entire cleansing work was assumed by the city authorities In the course of time privies and wet ash pits were abolished in favor of water-closets and dry ash pits. Power to close up all ash pits and replace them with portable galvanized bins was obtained under the building regulations act of 1900 In that year the change from ash pits to portable bins was commenced and up to May 31 1909 11 906 pits have been abolished and replaced by 39 365 bins Under the act property owners are required to abolish their ash pits also to pay for the bins and their maintenance

The refuse is now conveyed direct to a covered cart from the bin thus avoiding the pollution of the atmosphere and the nuisance of light material being scattered by the wind Refuse dispatch works and destruction furnaces were gradually erected for the disposal of refuse and the unsightly and unsanitary gigantic heaps of accumulated filth in the open depots soon disappeared

At the nine dispatch works the refuse is treated mechanically The portions fit for sale as manure are separated from the lighter and unsalable parts which are cremated in furnaces designed for the purpose The process of treating the refuse at the works is briefly as follows

Great quantities of soft sweepings require to be dealt with in wet, dirty weather These sweepings are tipped into brick built tanks with sloping bottoms fitted with perforated draining plates so that in the course of a few days the material which is chiefly composed of horse manure mixed with other refuse becomes solid enough to be transferred to a railway car

The domestic refuse is discharged from the carts through apertures in the floor into revolving screens fixed horizontally A mixing machine beneath catches the finer parts of the refuse that pass through the screen

Dry sweepings from paved streets are screened and mixed in a similar manner and from a tank above a regulated quantity of excrementitious matter passes into the mixer and when all is thoroughly blended it falls into a railway car on a siding below The coarser parts of the refuse are forced from the screen by the revolving process onto an endless carrier which drops them to a range of furnaces on a lower level As the carrier passes on everything of value is picked off such as scraps of iron wire bottles glass bones rubber tin cans galvanized and enameled ware etc The corporation owns 700 railway cars which they use for the conveyance of the city refuse over the various systems and this process of separation is in operation at 4 stations

The total quantity of material collected and disposed of by the department during the year ended May 31st 1909 amounted to 358 972 tons 8½ hundred weight The revenue derived from waste materials taken from city refuse and scrap from workshops and stores during the year ended May 31st 1909 was Clinker $81 916 tins and galvanized buckets and light iron $26 249 scrap iron $38 67[illegible] waste paper $32,694 bottles $1 279—total $180 81[illegible]

Prior to 1897 clinker was considered to be of no value and was trucked into the country at a cost of 24 cents per ton Introducing it to builders for concrete work resulted in creating a demand for clinker for that purpose The revenue from clinker alone has grown from $1,200 in 1897 to $8 895 in 1909

Old tins and galvanized and enamel articles which in previous years gave great trouble and annoyance to the cleansing department now produce a substantial revenue annually All old tin articles are now detinned and the remaining steel is pressed into solid billets by hydraulic power

At each station there is an inexpensive brick built furnace for removing the tin and solder The material is then conveyed in a motor vehicle to a hydraulic press and pumps at one of the stations where it is pressed into billets In the process of cremating the refuse more than sufficient power is generated to drive the clinker crushing machinery and to furnish electricity for lighting the destructor stations stables and offices

In 1900 the system of collecting waste paper by means of old bags issued to business premises and better class dwelling houses was inaugurated By this method the paper procured is clean and consequently more valuable than that taken from dust bins and to a great extent obviates the nuisance connected with its removal The revenue from this source has grown in ten years from $580 to $1 [illegible]00 This is a remarkable increase in view of the fact that private firms paper stock merchants are competitors of the corporation

In fifteen years the total revenue from the utilization of waste products has increased from $1 000 to $22 [illegible]00 All domestic refuse and garbage from hotels restaurants etc in the city are collected during the night concurrently with the street sweeping done by the sweeping machines There are bins sunk in the pavement at regular intervals in which are deposited the sweepings of the day staff These bins are emptied nightly and the contents together with the sweepings left at the street side by the sweeping machines are carted away

Private streets and back courts after being swept when required are cleansed by use of 1½ inch hose attached to the street fire plugs The court washings in the city average over [illegible]0 per day The proprietors of these properties are assessed 2 cents per $4 86 of the annual rental to meet the expenses of this work

After a heavy snowstorm in order to avoid disorganization of the street traffic and great inconvenience to the public the snow must be removed without delay consequently at such times great activity prevails in the cleansing department Salt is used to melt the snow on the tram tracks and is followed shortly afterward by the sweeping machine which spreads the brine created by the action of the salt on the snow over the entire width of the street thereby rendering it possible to clean the streets quickly The snow and slush is then rapidly carted and tipped into the rivers Clyde and Kelvin or the most convenient of the various tips around the outskirts of the city

In general the cities and towns throughout Scotland have well regulated cleansing departments similar to that of Glasgow with the exception that the smaller towns and villages have no furnaces for destructive purposes Some consume their garbage at county furnaces and others are obliged to cart it into the country

The city of Glasgow with its population of over 8[illegible]0 000 is perhaps all things considered one of the best cleansed cities in the world It has an excellent up to date sewerage system an abundant supply of pure water and its municipal government is of high order

* From Consul J N McCunn

A Four-Carbon Arc Lamp for Triphase Circuits

In 1904 Mercanton invented an arc lamp consisting of three specially devised and non homogeneous carbons connected severally with the three wires of a triphase circuit

Bentiroglio and Siciliani have studied three types of triphase arc lamps regulated by two magnetic fields rotating in opposite directions

Righi has recently invented a new type of triphase lamp, which produces a very constant and effectively distributed light, without the employment of complicated regulating devices Three carbons about 1/25 inch in diameter are mounted vertically with their points up so that they form the edges of a triangular prism, the base of which measures about 3/5 inch on each side Each of these carbons is connected to one of the three wires of the triphase circuit Above these three small carbons a fourth carbon about 1 inch in diameter is suspended so that its axis coincides with that of the prism As this arrangement allows the three lower carbons to make contact simultaneously with the upper carbon it is easy to establish three arcs, arranged radially and six craters The greater part of the light of an arc lamp is emitted by the craters. In the Righi triphase lamp, owing to the position of the three upper and more [illegible] craters most of the light is radiated downward without the [illegible] of the reflectors which [illegible] with [illegible] lamps.

[illegible] can be [illegible] transformers with their secondary circuits connected as a △ or as a Y Although the construction of a regulator with two rotary fields presents no serious difficulty Righi employs a simple hand regulator

If three intermediate arcs are formed among the three lower carbons with the central carbon raised high and the central carbon is then lowered until three arcs are formed between it and the lower carbons, no great variation in the emission of light or the consumption of energy is observed during the movement As soon as the three craters of the central carbon have been formed, however the consumption of energy is usually diminished and the light hitherto flickering and poorly distributed becomes steady and is greatly intensified and distributed more effectively

The central carbon is consumed very slowly and in certain conditions its craters are replaced by excessively bright protuberances which point toward the lower carbons

The Mercanton triphase lamp can be operated with a frequency as low as 17 alternations per second owing to the close approximation of its three craters and the fact that at least two arcs are always active As the Righi lamp has six craters and produces a still greater concentration of heat, it can probably be operated with still lower frequencies The importance of this point becomes evident when we recall that the minimum frequency that can be used with a motionless lamp is about 26, and that most triphase traction systems have a frequency of 15

No very certain results have yet been obtained from attempts to operate the Righi lamps with the low frequency rotor currents of an asynchronous triphase motor as the frequency varies with the load and it is very difficult to keep it constant but the inventor intends to resume the experiments as soon as more favorable conditions can be established —Revue des Sciences

---

The following note appears in a consular report for the year 1909 on the foreign trade of China In view of the almost limitless possibilities which seem to exist in China especially in the great plains of the north for the use of agricultural machinery it is with reluctance that one has to record the opinion that under present conditions there is really no opening for its successful introduction The financial risk attending the purchase of such machinery for the Chinese has been proved in several instances and British firms in China have to be careful how they repeat similar experiments Certainly British manufacturers desirous of introducing agricultural machinery into China would have to be prepared to share the risk with their agents to a much greater extent than they show any signs of doing at present But the subdivision of farms among small peasant proprietors who are extremely conservative in their methods the cheapness of human labor and the absence of effective organization of agriculture on the part of the Chinese government are among the conditions that discourage manufacturers from taking risks that experience has not justified"

The Paris Automobile Show*

The First Exhibition Held by the Manufacturers Themselves

Shorn of some of its former glory and inaugurated under a new management the Paris Salon of 1910 which closed on the 18th instant was altogether a different Salon from the last which was held two years ago Nothing of the sort held in Paris could in the nature of things be anything but spectacular and the present show is striking and in many respects characteristic But the uniform system of decoration adopted had the effect of breaking up the vista of the Grand Palais and in itself was more or less con fusing

The show itself was lacking in one of the features that in he past has rendered it the show of shows. In common with all shows of the day but to a more notable degree it lacked the element of extreme nov elty not to say freakishness in cars bodies and accessories The rare imagination of the French was of Knight, yet each of them has peculiarities all its own For example in the Roland Pilain but one sliding sleeve is employed instead of two as in the Knight engine the motor otherwise resembling the Knight in many respects Incidentally it may be mentioned that the Roland Pilain car in which was mounted a six-cylinder motor of the type in question was further distinguished by an equipment of hydrau lic brakes which were applied to all four road wheels.

In the case of the motor shown by Mustad et Fils the valve construction was equivalent to a single sleeve split in half vertically Each half sleeve carrying a suitable port opening as in the Knight engine is actuated independently from one of two eccentric shafts In the new Cottereau motor a single sleeve likewise is deemed sufficient but instead of being made to travel up and down the cylinder bore as is the proper instant of the cycle. Unlike the Corliss valve however it does not oscillate, but revolves. Hence by placing one of the passages above and the other below the valve chamber the single member is made to serve both the inlet and the exhaust. A com mendable point in the design is that the port is placed somewhat below the upper end of the piston travel in the cylinder so that the valve is relieved of excessive pressure during the beginning of the firing stroke

The Boissier motor likewise is furnished with a form of rotary valve termed a distributor in this instance, which is mounted above the cylinders and which as it is carried in ball bearings offers very little frictional resistance Owing to the relatively large size of the distributor and its casing the motor is given a curious and rather top-heavy appearance, which is not in the least relieved by the vertical mo-

THE PARIS AUTOMOBILE SHOW

apparent in many instances it is true but not to its former extent. For the most part the exhibits were rather conventional in their nature and sweeping trends were lacking There were 350 stands or less, 125 of which were occupied by exhibitors of cars The accessory and components exhibits which composed the remainder for the most part were those of the established manufacturers and dealers who showed more or less standard wares. But two American makes of cars were in evidence namely the Mitchell and the Ford

If the show may be said to have developed anything in the way of mechanical tendency it is in the so-called "valveless motor—which is not a valveless motor at all but one having either sliding or rotary valves instead of those of the common or poppet type. There were practically a dozen different motors of this class to be seen including one or two that were shown in the balconies and also including the Panhard Mercedes and English Daimler cars which are equipped with variations of the Knight engine

Several of the engines which fall within the valveless classification appear to have been designed by followers done in the case of the valve systems previous y men tioned the valve sleeve is merely caused to revolve in a suitable recess which is formed in the cylinder wall The single port opening in its surface thus is made to register alternately with the inlet and exhaust open ings The Sizaire et Naudin formerly distinguished as a light voiturette with a huge single-cylinder motor now is built in the form of a light and more conven tional machine and is equipped with a motor of the 'valveless' type

Among the engines which reveal more radical departures from precedent, perhaps none attracted more attention than the Henriod partly it is to be inferred for the reason that its constructor in the past has distinguished himself by several unfettered flights of fancy in the way of novel design In this case how ever there is nothing irrational about his achievement, which is, nevertheless distinctly radical. It is, in brief a form of rotary valve which is broadly suggestive of the Corliss steam engine gear That is to say the valve itself is a D-section, though revolving in circular bearings, the flat side of the "D" serving to uncover the single port in the cylinder wall and to open communication with the intake or exhaust at tion shaft and the housing for the helical gears by which the distributor is actuated Still another motor of the rotary valve type is the Ballo in which the valves are of hemispherical formation and oscillate instead of rotating Their movement is brought about by cam action the valve motion shaft and cams being inclosed in a housing above the cylinders, which is of peculiar and characteristic shape.

By all odds the most original, not to say freakish, design to be found was that of the Broc motor in which the effects of a sliding valve and a rotary valve are achieved after a most curious fashion. The distribution is effected by the simple expedient of converting the piston itself into a valve and causing a portion of it to revolve in the cylinder in addition to its reciprocating motion. A helical groove is formed in the outer part which leads from the base to a point just below the head, where a hole is cored through to a couple of ports in the head proper. The intake and exhaust ports, of course, are located in the lower part of the cylinder.

As a matter of fact, the piston is [illegible]

*Reprinted from the Motor World.

wrist pin and connecting rod, and does the work of driving. The secondary part is a surrounding sleeve, in which the helical groove is formed, and which is rotated by means of a bevel gear on the lower end of a tubular shaft which telescopes the connecting rod and is driven by a stationary bevel gear attached to one of the crank webs. As the piston reciprocates the outer or valve portion is reciprocated with it and also is rotated to effect the distribution. Thus the motor is valveless only so long as the outer portion of the piston is by courtesy considered a part of this piston and not a valve

Among other points observed at the show was the apparently growing inclination of the French builders as well as those of other Continental countries, to construct cars well within what is broadly termed the medium-powered class Particularly noteworthy at this time indeed are the numerous cars of 16 to 30 horse-power nominal rating and especially those of somewhere about 20 horse-power The block method of casting continues to grow in popularity and not a few six-cylinder motors of relatively low power now are made in this fashion Among such may be enum

Another observation was the periodical decline of the voiturette which again appears to be passing into obscurity after a season of renewed popularity The bulk of the European trade appears to be in cars of the medium class all through and though closed cars continue to gain in popularity the favorite styles are those in which the entire vehicle is inclosed whether they afford accommodation for two or more passengers The torpedo styles of touring car and runabout have come into vogue and the influence of the torpedo is seen in many forms of closed cars

A remarkable instance in point is that of a Gregoire car which is built on thoroughly approved marine lines, with a ridiculously small body superstructure mounted in the center in close semblance to the conning tower of a submarine Another remarkable achievement of the body maker s art is the 120 horse-power Pipe the front of which slopes from a point immediately above the driver s head to the dash thus giving the machine the appearance of having just come through some dire catastrophe in which its front portion had been sadly crushed A body which is far more appealing if somewhat less striking in its

hood after a fashion introduced by at least one maker in this country last year separate spring suspension for the radiator and brass covers for the joints in the steering connections are novel and interesting details that were to be observed on various cars

The general details of transmission and other chassis features reveal few striking changes in the new designs Universal joint construction in many instances has been revised with the idea of obtaining better durability and freedom from wear and in this connection the Isotta Frashchini universal is particularly noteworthy It consists of nothing more complicated than a disk of stiff leather which forms the sole connection between the flanges of the driv ng and driven members of the joint Besides allowing perfe t flexibility and small resistance this device has the advantage of being abso utely noiseless

The new type universals on the lates Rens it designs are housed in a neat alumini m asing The rear springs of the new hassis shown t h Salo are of the three-quarter elliptical pattern b t with the lower or semi-elliptical members slu g beneath the axle thus affording a very low center of gravity

erated the Delage which is rated at 16 horse-power and has a bore and stroke of 66 by 12 millimeters or roughly 2⅝ by 5 inches and the Delahaye which is rated at 18 to 24 horse power and has its cylinders arranged in V form in two groups of three but all cast together the cylinder dimensions being 75 by 120 millimeters, or 3 by 4 13/16 inches Other small six-cylinder motors but those in which the cylinders are cast in pairs or in blocks of three are the 17 to 20 Mors 16 Motobloc, 20 horse-power Darracq—a worm-driven model it may be explained—15 horse-power Clement Bayard and 12 horse-power Delaunay Belleville the last has cylinder dimensions of 72 by 120 millimeters or about 2⅞ by 4 13/16 inches

Two marked effects of the new style construction which is expressed in the popular form of block motor also are beginning to be apparent in other types as well. One is the desire to secure a clean" engine by stowing away the auxiliaries as neatly as possible and relieving the exterior of the cylinders of any needless encumbrance. The other is to extend the stroke. [illegible] abnormally long strokes by no means are the [illegible] also by no means uncommon, while the [illegible] seems to be to increase the bore-to-[illegible]

appearance is the Fiat obus which is a Rothschild creation and which besides being of the most sumptuous order is built with an eye to cleanliness and freedom from unnecessary windage

The Gregoire aviator body is strictly a double coach and has much the same effect as would be secured by mounting two sedan or coupe bodies on the same chassis Needless to add it is of the two-compartment type as distinguished from many of the newer bodies in which there is but a single door on either side and no dividing partition between the front and back seat spaces

Among various individual body refinements may be mentioned one particular runabout body mounted on a Gobron chassis, which is provided with a deep scuttle dash Under ordinary circumstances there is nothing to indicate that the dash is in any way extraordinary But when it is desired to carry a chauffeur one side of the scuttle may be removed disclosing a neat folding side seat into which a small or medium-sized chauffeur may be squeezed without serious inconvenience and where he will be handy in case a tire goes down or the engine becomes obdurate

Ventilated dashes for the inclosed torpedo bodies electric lights built into the dash or the front of the

Three-quarter ellip ic s spensions by the way are growing in popularity

Shaft drive is employed almost exclusively as is magneto ignition Thermo syphon cooling likewise is becoming exceedingly popular while automatic self contained engine oiling systems are the rule

In addition to the Sizaire et Naudin change gear which is of unique construction and mounted on the rear axle one other peculiar axle mounted change gear was in evidence—that of the Miolans car in which the speed changes are effected by ca sing a single driving pinion to mesh with one or another of three sets of teeth on the large driven gear the teeth naturally being of peculiar formation in order to render this combination possible But one friction drive was in evidence that of the Ouricum which employs the two-disk principle

Dentists Modeling Wax —Twenty five parts of pale gum copal are melted in the sand bath and when half cooled 25 parts of stearine are stirred into it and dissolved Then stir in 50 parts of Venetian chalk and 0.5 part of carmine perfuming it with 2 drops of oil of roses

The Development of Submarine Boats*

From Bushnell to Holland and Lake

By Simon Lake

When the United States government in 1893 advertised for inventors to submit designs for the construction of a submarine torpedo boat it is doubtful if a corporal's guard of officers in the United States service could have been found that had any faith in this type of vessel

The submarine boat at that time was considered as great a curiosity by the majority of people as the flying machine was previous to the public flights of the Wright brothers a little more than a year ago At that time neither the United States England Russia nor any of the European countries were in possession of what might be termed a practical submarine vessel

The French government had one experimental vessel in commission called the Gymnote and another under construction which was called the Gustave Zede The latter was launched in June 1903 Both these vessels were of the diving type and operated on the same principle as numerous others that had been experimented with during the nineteenth century

The records show that nearly a hundred submarine boats have been projected or built to operate on practically the same principle as the Gymnote most of them vessels of small size Drzwiecki the inventor of the torpedo firing apparatus which bears his name built a large number of small vessels of this type for the Russian government in the seventies They were one-man boats

Several boats were built by the Confederates during the Civil War which operated on the same principle The attempts to use these vessels however usually resulted disastrously the boat having a tendency to dive head first to the bottom in some cases remaining there permanently especially if the bottom was soft If the bottom was hard and the hull was sufficiently strong to withstand the shock the vessel would rebound to the surface

Hovgaard in his book on submarine navigation refers to one of the early French boats of the diving type called Le Plongeur This boat was the most ambitious attempt to construct a submarine vessel during the nineteenth century She was about 140 feet long 20 feet broad and 10 feet deep Her beam was therefore twice her depth She had an oval form in cross section and was presumably braced to resist the pressure of water when submerged This form of hull would need to have been strongly braced to resist collapse at any considerable depth as her plate was said to be only ½ inch near the keel and ⅜ inch throughout the rest of the vessel She was propelled by a compressed air engine which developed 80 horse power when working with air at twelve atmospheres It is stated that the engine always worked well Her displacement was about 200 tons In his description of this vessel Hovgaard says

The greatest difficulty was the regulation of the motion in a vertical sense Operations commenced by closing all openings and then water was let into the two air reservoirs and into the water-tight compartments until only the top of the conning tower was above the surface It was found to be pretty easy to go like this awash along the surface of the sea It was expected that the depth of immersion could be determined by small changes in displacement namely by using the piston in the regulating cylinder but the experiment showed this to be quite impossible and the vessel would often touch bottom even in 30 feet depths before the motion could be changed When striking tolerably hard bottom such as sand the vessel would rebound like an India rubber ball Thus the 'Le Plongeur' would advance striking alternately the bottom and remounting to the surface

The horizontal rudders and the regulating cylinders acted much too slowly Most frequently they had to resort to the donkey pump or to air pressure to expel water but then the ascension would take place very violently and when at the surface, the vessel would be found to have a buoyancy of several cubic meters A vertical screw was therefore fitted to regulate the motion up and down It was worked by hand In this way the equilibrium under water was kept, but only for a very short time

The result of the experiment was that it was possible to make a submarine boat slide along the bottom in the way described above and also to move steadily awash.

It will be seen from the above description, and the abandonment of the vessel that this boat, like many others of the type was unmanageable when attempts were made to run her in a submerged condition With her shallow depth and great beam it is probable that the failure of this vessel was largely due to a lack of longitudinal stability which stability in my estimation is the first and most important thing in the designing of a suitable vessel.

The Confederates attempted to use the submarine boat during the Civil War and succeeded in sinking one of the United States warships They called the little submarine boats which they constructed at that time Davids and the name was a most apt one The next war will probably prove that the submarine Davids will be able like David of biblical fame to destroy the great Dreadnaughts or Goliaths, of the present day

Previous to the beginning of the nineteenth century some experiments had been made in the construction of submarine vessels. The first important one of which there is any record was constructed in the seventeenth century by Cornelius Debrell a Dutch man who lived in England during the reign of James I Nearly a hundred years later a man by the name of Day built a submarine and made a wager that he could descend to a depth of 100 yards and remain there twenty four hours He did, and according to latest advices is still there

The most authentic information at hand however regarding the early submarines is of a boat built by a Connecticut man Dr David Bushnell who lived in Saybrook during the Revolutionary War He built a small submarine vessel called the "American Turtle with which he expected to destroy the British fleet anchored off New York during its occupation by General Washington and the Continental Army

Thatcher's Military Journal" gives an account of an attempt to sink a British frigate the Eagle of 64 guns by attaching a torpedo to the bottom of the ship by means of a screw manipulated from the interior of this submarine boat A sergeant who operated the Turtle succeeded in getting under the British vessel but the screw which was to hold the torpedo in place came in contact with an iron strap refused to enter and the implement of destruction floated down stream where its clockwork mechanism finally caused it to explode throwing a column of water high in the air and creating consternation among the shipping in the harbor Skippers were so badly frightened that they slipped their cables and went down to Sandy Hook General Washington complimented Dr Bushnell on having so nearly accomplished the destruction of the frigate

If the performance of Bushnell's "Turtle was such as described it seems strange that our new government did not immediately take up his ideas and make an appropriation for further experiments in the same line When the attack was made on the Eagle Dr Bushnell's brother who was to have manned the craft was sick, and a sergeant who undertook the task was not sufficiently acquainted with the operation to succeed in attaching the torpedo to the bottom of the frigate. Had he succeeded, the "Eagle" would undoubtedly have been destroyed and the event would have added the name of another hero to history and might have changed the entire method of naval warfare Instead of Bushnell being encouraged in his plans however they were bitterly opposed by the naval authorities His treatment was such as finally to compel him to leave the country but he returned after some years of wandering and under an assumed name settled in Georgia, where he spent his remaining days practising his profession.

Robert Fulton the man whose genius made steam navigation a success was the next to turn his attention to submarine boats and submarine warfare by submerged mines A large part of his life was devoted to the solution of his problem He went to France with his project and interested Napoleon Bonaparte who became his patron and who was the means of securing sufficient funds to build a boat which was called the 'Nautilus." With this vessel Fulton made numerous descents, and it is reported that he covered 500 yards in a submerged run of seven minutes

In the spring of 1801 he took the "Nautilus" to Brest and experimented with her for some time. He and three companions descended in the harbor to a depth of 25 feet and remained one hour, but he found the hull would not stand the pressure of a greater depth. They were in total darkness during the whole time, but afterward he fitted his craft with a glass window 1½ inches in diameter, through which he could see to count the minutes on his watch. [illegible] discovered during his trials that the [illegible] pass pointed equally as true under water as [illegible]

His experiments led him to believe that he could build a submarine vessel with which he could swim under the surface and destroy any man-of war afloat. When he came before the French Admiralty however, he was met with blunt refusal, one bluff old French admiral saying 'Thank God France still fights her battles on the surface, not beneath it, a sentiment which apparently has changed since those days as France now has a large fleet of submarines. After several years of unsuccessful efforts in France to get his plans adopted, Fulton finally went over to England and interested William Pitt, then chancellor, in his schemes He built a boat there, and succeeded in attaching a torpedo beneath a condemned brig provided for the purpose blowing her up in the presence of an immense throng Pitt induced Fulton to sell his boat to the English government and not bring it to the attention of any other nation, thus recognizing the fact that if this type of vessel should be made entirely successful, England would lose her supremacy as the Mistress of the Seas'

Fulton consented to do so but would not pledge himself regarding his own country stating that if his country should become engaged in war no pledge could be given that would prevent him from offering his services in any way which would be for its benefit.

The English government paid him $75 000 for this concession Fulton then returned to New York and built the Clermont' and other steamboats but did not entirely give up his ideas of submarine navigation and at the time of his death was at work on plans for a much larger boat.

Fulton had a true conception of the result of submarine warfare and in a letter he says Gunpowder has within the last three hundred years totally changed the art of war and all my reflections have led me to believe that this application of it will in a few years put a stop to maritime wars give that liberty on the seas which has been long and anxiously desired by every good man and secure to Americans that liberty of commerce tranquillity and independence which will enable citizens to apply their mental and corporeal faculties to useful and humane pursuits to the improvement of our country and the happiness of the whole people

After Fulton's death spasmodic attempts were made by various inventors looking to the solving of the difficult problem but no very serious efforts were put forth until the period of the Civil War and then a number of submarine boats were built by the Confederates These boats, as already referred to were commonly called 'Davids and it was one of them that sank the United States steamship Housatonic in Charleston Harbor on the night of the 17th of February 1864 This submarine vessel drowned four different crews a total of thirty men during her brief career At the time she sank the Housatonic" her attack was anticipated and sharp lookout was kept at all times but notwithstanding their vigilance she succeeded in getting sufficiently close to plant a torpedo on the end of a spar and sink this fine, new ship of 1 400 tons displacement.

According to one of the officers of the 'Housatonic ' the attack was made in the following manner "About 8 45 P M the officer of the deck, Acting Master M K. Crosby discovered something in the water about a hundred yards away coming directly toward the ship, the time from its appearance until it was close alongside being about two minutes, during which time the chain was slipped, engine backed, and all hands called to quarters. The torpedo struck the ship forward of the mizzen mast on the starboard side, in line with the magazine, and as we had the after pivot gun pivoted to port, we were unable to bring a shot to bear upon her About one minute later she was close alongside and the explosion took place the ship sinking stern first, and heeling to port as she sank. Most of the crew saved themselves by going into the rigging while a boat was dispatched to the 'Canandaigua.' The vessel came gallantly to our assistance and succeeded in rescuing all but a few of the officers. What became of the 'submarine boat' was a mystery not solved until a few years ago, when some divers in searching about the wreck of the sunken steamship found, a few feet away from her, the 'David' with skeletons of her crew still abroad. It was found that the hatch was open, and it is supposed that the water thrown up by the torpedo caused her to founder with all hands."

It will be observed by the above [illegible] [illegible]

* Proceedings of the Engineers Club of Philadelphia.

to maneuver the boat sufficiently near the "Housatonic" to prevent discovery until too late to ward off the attack.

The author was fortunate enough several years ago to receive a visit from Mr Charles H Hasker of Richmond, Va. formerly lieutenant of the Confederate ironclad "Chicora," stationed in Charleston Harbor While experiments were being made with the submarine vessel just described Mr Hasker volunteered as one of the crew for the experimental trip about the river, and was one of four that escaped when the vessel went down He gave me the following account of her sinking

"The submarine had a line fast to the steamer Etawan off Fort Johnson the crew were all in their places, and had started the craft ahead The buoyancy of the vessel had been reduced so that only the hatch combings were above the water The side submerging vanes were operated by a tiller connected with the athwartship shaft, and were held in a horizontal position by means of a stick of wood placed beneath When the vessel started ahead Lieut. Paine attempted to cast off the line which was made fast around the hatch combing He became entangled in the line causing the boat to sheer slightly and careening her sufficiently to permit the water to come in the forward hatch. The lieutenant in his struggles to extricate himself, struck the prop which supported the ends of the tiller thus causing it to drop to the floor and forcing the forward ends of the vane downward This of course immediately pulled the bow of the boat under water Mr Hasker occupied the forward seat just at the hatchway Lieut Paine succeeded in getting out as soon as he saw the boat was going to sink and Mr Hasker grasped the edges of the hatch combing and finally forced his way through the column of inrushing water which was by this time coming in with great force But before he was entirely out of the opening the pressure of the water closed the hatch door which caught his left leg below the knee The pressure of the water was so great against the door that it crushed the muscles of the leg and held him in this position until the vessel had reached the bottom in seven fathoms of water The hull then being filled with water equalized the pressure so that he was able to lift the door and being an expert swimmer he swam to the surface The boat went down head first and before the after hatch got under water two other men succeeded in escaping the other five being drowned

Notwithstanding that this was the third time the boat was sunk she was again raised and a new crew was found to man her Mr Hasker states that he was unfortunate enough to be captured at the evacuation of Morris Island about one week after this occurrence was kept prisoner for fourteen months and was at Hilton Head prison when he heard that the submarine had finally accomplished her mission in sinking the U S S Housatonic

This brings us to 1893 and to the more recent attempts to solve the problem of submarine navigation which at the present day is an accomplished fact and every nation of importance is adding submarine torpedo boats to its fleet for purposes of defense and many of them are even now proposing vessels for offensive as well as defensive purposes

In 1877 Mr John P Holland built a small boat which was called the Fenian Ram It is stated that this vessel was built by capital furnished by the Clan na Gaël with the idea of using it against the British fleet in an attempt to free Ireland It is reported that Mr Holland who was a school teacher had been exiled from that country because of his political activity From the published description of this boat it would appear to be very similar to the small boat turned out by Drzwiecki for the Russian government in that it operated with a vertical and a horizontal rudder in the same manner as other boats of the diving type which have been mentioned

Previous to the appropriations made in 1893 Mr Holland had built several small boats of this type and it is reported that he met with considerable success in navigating them

Mr Baker of Chicago had built a vessel of quite a different type. His boat was elliptical in shape and in form resembled the "Goubet' type of vessel It was propelled by screws located about midship on either side of the vessel These screws were operated by gear wheels in such a manner that the angle of thrust could be changed to submerge the boat, the vessel having a certain reserve of buoyancy, the propellers could be set at such an angle as to cause the vessel to submerge until she reached a given depth and then, by slightly reducing the angle, the vessel would move forward theoretically on a straight course and on a line which would be a mean between the upward pull due to the buoyancy of the vessel and the downward and forward pull due to the inclination of the propellers

It is reported that this vessel made a number of successful trials in the waters of Lake Michigan The form adopted by Baker was one well adapted for giving great stability but was not suited to speed It was largely due to Baker's success however and to the report made by a board of officers which watched the performances of this craft in 1892 that the first appropriation of $200 000 was made for the construction of the United States submarine When the appropriation was made Baker was so sure of receiving the award for the contract that he moved from Chicago to Washington with the idea of being close to the government authorities while developing the plans for his large vessel He died shortly after moving there Mr Holland Mr Baker and the author it is believed were the only inventors of submarine craft that were present with plans in Washington at the opening of bids in June 1893 The author did not submit a proposition to build a vessel as the advertisement stated that the department would consider designs even if they were not accompanied by tenders for construction and if the designs were considered meritorious the department would itself arrange for the construction of the vessel The author's designs were submitted to a board to pass upon their merits and he was later advised by the late Admiral Matthews that his designs were looked upon with considerable favor by some of the members of the board at that time but as the Holland designs were accompanied by a bid to construct with a bond for performance backed by a company the Navy Department was reluctant to take upon itself the responsibility of the development of a vessel from designs only The matter of awarding a contract was held in abeyance for over a year and finally the award was made to the Holland Company for the construction of the Plunger on certain guarantees of performance which guarantees were destined never to be fulfilled under the first contract as this boat the Plunger was to have done many things that even to this day have never been accomplished by any submarine boat She was to have a speed of about 16 knots and be able to go from light condition to that of complete submergence in twenty seconds Her construction extended over a period of several years and she was finally abandoned in 1900 after the Holland Company had received additional appropriations and brought out a much simpler vessel in the Holland the first United States submarine torpedo boat which went into commission

The first Lake design was of a submarine boat previously referred to and was submitted to the United States Government in 1893 in response to a public advertisement asking inventors to submit bids for submarine boats for the United States Government

Some of the features of this design were two hydroplanes on either side at the bow and the stern with fore-and-aft rudders for correcting trim There were wheels for navigating on the bottom This boat was fitted with four torpedo tubes two forward and two aft

The Holland was the first United States submarine boat and is the boat previously referred to which took the place of the Plunger the first United States boat contracted for This type of boat operates in the same manner as the early French and Spanish boats It also operates on the same principle as the Whitehead torpedo except that the intelligent control of man operates the vertical and horizontal rudders rather than automatic appliances The principle of operation however is the same

These boats are still built in the cigar-shaped form which is without doubt the best form for under water speed but has certain disadvantages as a surface sea going craft, and is more difficult to control when operating submerged The earlier boats of the Holland type were lacking in stability and were very erratic as to their performance having a tendency as did the early boats of the same type constructed in France and Spain and as did the boats of similar type before referred to that were constructed during the Civil War either to run their nose into the bottom or to broach to the surface

These vessels have been much improved however in the last three or four years owing to the greater experience in their design and construction and the necessity now—since competition has been permitted in the securing of submarine vessels for the United States navy—of providing vessels that will meet the requirements of the United States naval authorities The standard of performance now required by the United States navy is the most severe of any country

Early in 1901 the author received a request to come to Washington and submit designs to the navy department for the construction of submarine torpedo boats of the Lake type as the department was not satisfied with the performance of its Holland type of submarine then The designs of the Protector and of the cruiser type of boat were submitted to the Board on Naval Construction at that time composed of five admirals and the author was informed that his designs were considered superior to anything yet proposed in the way of submarine boats either in this country or abroad Congress had always specified Holland boats notwithstanding the protest of many officers in the navy department It was suggested however that if a submarine boat were constructed with private resources it was within the power of the navy department to see that such a vessel would be given a fair trial when completed and that the department could make such recommendations as were impossible for Congress to ignore On the strength of these promises the author started to construct the Protector

The later German Krupp boats are fitted with the buoyant superstructure and hydroplanes The latest boats are fitted with omniscopes

One of the features of the Lake type of boat has been that it carries its fuel outside of the living quarters of the crew in especially designed tanks in the superstructure which tanks are galvanized to prevent the escape of dangerous fluids or gases Both the German boats and the Italian boats have adopted this feature the only difference being that the fuel tanks were built up directly over the hull of the vessel rather than being built circular in form and galvanized after construction It appears that the fuel leaked through this built up tank in the Italian boat Foca down into the hull where it became ignited and caused an explosion which blew up the vessel and killed her crew of twenty three men This was probably due to some careless workmanship or neglect on the part of some members of the crew to take proper precautions in seeing that the pipe connections where they came through the hull were properly made It is impossible to provide against the ignorance and carelessness of workmen and members of the crew Many explosions have occurred both in this country and abroad on submarine boats and numerous lives have been sacrificed which with a little more thought and care might have been saved

There are a number of dangerous things in connection with submarine boats The gas which is given off in large quantities from the batteries is hydrogen and is very explosive If the fumes of the gas are not pumped out as rapidly as they are given off an explosion is very likely to occur The fumes of gasoline when mixed with the proper proportion of air are also highly explosive For this reason Lake boats always carry fuel outside of the main hull and fortunately so far no lives have been lost on any of these boats although a number of men were nearly lost last August on the Russian submarine Dragon This was before the boat was entirely completed and was caused by the carelessness of one of the workmen in pouring several gallons of gasoline into the hull through an open pipe before the same was connected up The accident resulted in severe injuries to a number of the men and about $100 000 damage to the boat

The dangers of gasoline have brought about extensive experiments in trying to develop heavy oil engines for submarine boat service Hundreds of thousands of dollars have been expended in trying to produce a satisfactory engine of this class All governments are now calling for heavy oil engines and if experiments now well advanced prove their practic ability it will bring about a revolution in the construction of internal combustion engines not only for submarines but for all other classes of boats using liquid fuel

Two of the Lake boats, 161 feet long are under construction for the United States Government at Newport News One is the Seal the other is the Tuna. The Seal is the largest and most powerful submarine boat now under construction for the United States Government

(To be concluded)

During the year 1909 electric lighting contracts were given out for new installations at Chungking, [illegible], Nanking, and Ningpo, and for more or less important extensions at Shanghai (settlements and native city), Hankow, Peking, Swatow, [illegible] and other places. Negotiations were going [illegible] a large installation at [illegible] several cities in Manchuria. Indeed, there may be said to be an electric lighting project in every city in China although at Pakhoi the project is stated to have been abandoned in view of the successful introduction of incandescent mantles the only difficulty is to find funds for carrying such projects into execution Almost all contracts require to be financed by the contractors and British firms, finding British manufacturers unwilling to supply plant except for cash down have sometimes co-operated with German firms the latter arranging the finance in return for being allowed to participate Thus several of the contracts mentioned above are for British engines and boilers and German dynamos Payment is generally spread over a period of two or three years on proper security being given to the contractors

Jarman's System of Electric Traction by Storage Batteries

A Pioneer Electric Tramcar

The subject of electric traction by means of stored energy having come to the fore again because of the improved form of storage battery by Mr Thomas Edison the following historical account of a storage battery system of electric traction that proved to be a thoroughly practical one from every test that could be made either from an electrical or engineering standpoint as well as from a constructional view can but prove of value to many who are concerned with electric traction to-day

It was on October 25th 1886 that Mr A J Jarman invited a large number of editors and proprietors of the daily and technical press to witness the practical working of a model electrically propelled car at No 443 Brixton Road London England This model was fitted upon trestles at the back of the premises A considerable number attended and saw for the first time an electrically propelled vehicle

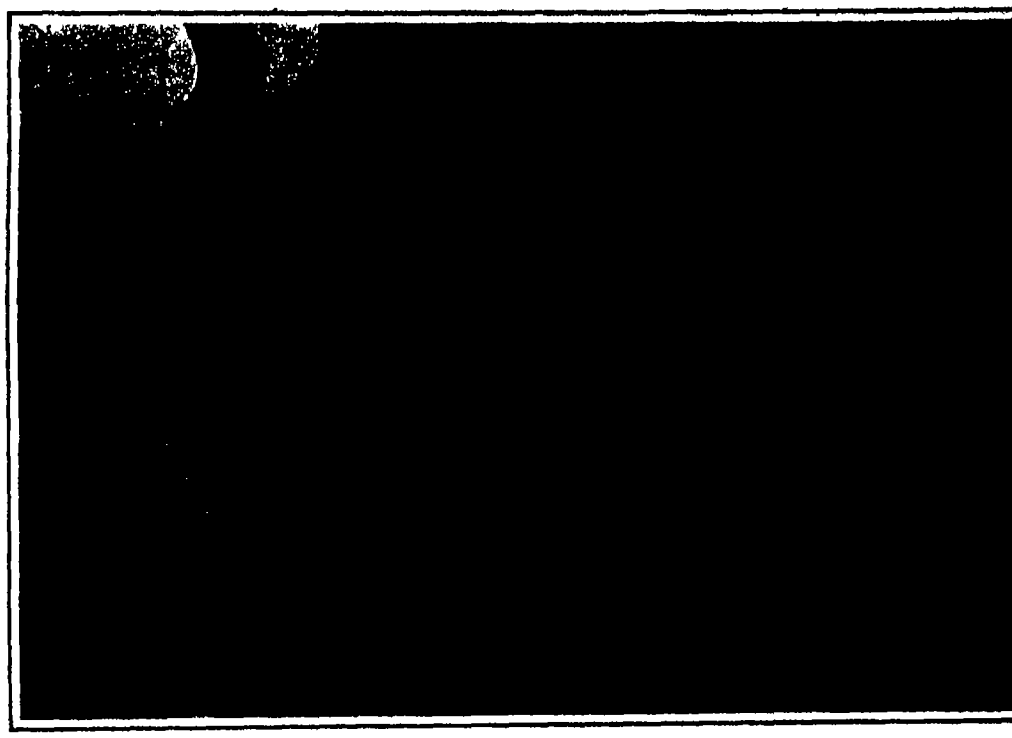
This model was 3 feet 7 inches long was driven with a double armature motor and thirty carbon zinc cells placed beneath the seats The car travelled at a speed of over five miles per hour The tests lasted from 11 o'clock A M until 3 30 P M satisfying every suggestion made by the representatives of the press One of the photographs shows the model and trestle tramway Another photograph shows the experimental passenger car that was made from a disused horse car of the London Tramways Company The car body alone weighed three (British) tons equal to 6 7 0 pounds the electrical equipment being in addition

The inventor designed built and fitted a motor to this car with a double armature which when completed was put on test by permission of the London Tramways Company after 12 midnight when the horse cars ceased running The trial took place in March 1887 and the car ran from Atlantic Road Brixton to Westminster Bridge and returned successfully in every particular carrying 45 passengers At the end of the journey this car was driven over the macadamized Atlantic Road from Brixton Road to Electric Lane without rails by its own power In November of the same year the car was deposited at the disused stables of the London Tramways Company at Clapham Cross where another trial took place The car was driven from Clapham Cross to Blackfriars Bridge and return (This was the first electrically driven car that ran to the above bridges of the city of London Upon another occasion this car carried 115 passengers from Westminster Bridge to Clapham Cross

The third photograph illustrates the car that was the outcome of every suggestion and improvement that the experimental car indicated Fitted with reversible top seats although constructed with seats for 44 passengers it carried upon many occasions as high as 86 passengers

This car was fitted with a compound bipolar motor of 14 horse power and compound gearing together with ampere meters and voltmeters at both ends of the car so as to enable the observer to note the actual electrical horse power used either upon a level or a variable incline The construction of the motor differed materially from any hitherto attempted The whole of the desired resistance was constructed within the windings of the field magnets no external resistance being used whatever The result was that only the necessary amount of electrical energy was employed to start the load without loss in a wasteful external resistance By this plan the car could never start with a sudden jerk

The following tests were made that proved the value of this part of the invention It may be mentioned here that the controller was so constructed that the forward and backward motion of the car was made by turning the handle to the right in four steps for forward and to the left for backward motion no extra controller being used as is the case upon many cars to day



MODEL OF ELECTRIC CAR ON THE TRESTLE TRAMWAY

MOTOR TESTS

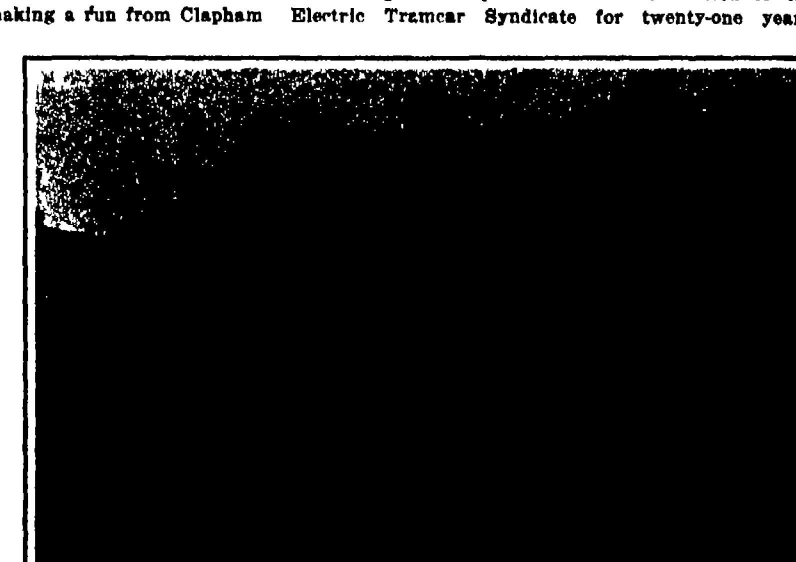
Ninety storage traction cells were used of the lead type with aluminium fittings

1 A current of 30 amperes was passed through the single motor and gave a torque or 60 pounds

2 Fifty amperes was next put through the same motor and gave a torque or 97 pounds

3 The motor was coupled as the inventor had designed All the windings being in series a current of 28 amperes was passed through which gave a torque of 117 pounds The above tests were made many times over upon a Prony brake These tests proved conclusively the economy in power production by this particular construction of motor At the latter end of September 1890 a thorough test of this car was made by making a run from Clapham Common to Tooting and back (at that time a new extension of the London Tramways Company's line) The number of passengers was 44, including several electricians from the Brush Electric Light Company and their chairman, the late Duke of Marlborough; the chairman of the London Tramways Company, D. P Sellar and all the directors, road surveyors, and engineers. The car was put to every test suggested, with complete success, with no hitch whatever Balham Hill was ascended upon the return journey which consists of a variable incline of 1 in 18 to 1 in 22 the current never exceeding 50 amperes, while as a further test this car pushed a horse car in front up the hill in addition to its load of 44 passengers. When running upon a level with wetted rails 5 to 8 amperes was the only energy used the speed being at the rate of ten miles per hour An exact account of this run was given in the Electrical Review London October 3rd 1890 .This car could be run off the rails put around a breakdown and on to the rails again Provision for this unusual work to be accomplished was made by the use of a pair of ramping irons and a lateral movement of the front axle the axle box being made specially for this purpose The cost of working by this storage system has been well tested and proved during a period of eight years When the time came for its general adoption upon the Clapham Tooting extension as stipulated and in accordance with the written promise of the tramway company (under a guarantee of eight and a half cents per mile) the London Tramways Company backed out and would not adopt it although their premises had been leased to the Electric Tramcar Syndicate for twenty-one years their excuse being that they had only six more years to run with their lease from the local authorities and thus an excellent, well-tested system came to a standstill after $15,000 had been spent, and eight years of incessant labor. These storage [illegible] like the Edison, and many [illegible] [illegible]

DISCARDED LONDON TRAMWAY HORSE CAR MADE INTO AN ELECTRIC PASSENGER CAR



VIEW OF ELECTRIC CAR PERFECTED THROUGH IMPROVEMENTS MADE ON CAR AT THE LEFT

York, were adopted The electrical efficiency of the motor proved to be 94 per cent in all the workshop tests. Although two of these cars were thoroughly tested afterward in every-day traffic upon the Croydon Tramway Company's lines running from Thornton Heath to Crown Hill on time with the horse cars the little syndicate was denuded of capital from the previous experience Entirely through these difficul ties the running of these cars ceased although many meritorious parts of the invention are being adopted by others to-day in electric traction The battery was lighter than any hitherto made and of high efficiency

Forms for Concrete

Schemes for Saving Time, Labor, and Lumber

SINCE freshly mixed concrete is a plastic material forms of some kind are necessary to hold it in place and in shape until the cement sets up and the con crete becomes hard. Lumber though expensive is the material most commonly used By exercising his natural ingenuity and customary care in the matter of construction of forms, the farmer has built so cheaply of concrete that his cost statements are frequently doubted by the builder in the city

Much of the work done on the farm requires almost no forms at all In this class are walks floors in buildings, and feeding floors.

The first requisite of good forms is that they should be tight, so that the liquid cement may not run out between the cracks, cause pockets or hollows and thus ruin the looks of the work as well as decrease its strength Consequently straight boards are most desirable unless one chooses to fill gaping cracks with stiff clay and tack strips over them. Dressed lumber is usually straightest and yields a neater finish to the concrete But for ordinary purposes rough lumber is sufficiently good Naturally the siding must be stiff enough not to bulge out of shape when the forms are first filled with concrete This does not mean that very heavy siding is necessary In fact 1 inch boards are usually sufficiently strong The bulging may be prevented by setting 2 by 4 inch studding from 20 to 30 inches apart according to the thickness of siding boards or sheathing used

The thoughtless cutting of boards into short lengths means a waste of lumber and a useless increase in the cost of concrete Unnecessary nailing not only calls for more nails but adds to the difficulty of removing and the danger of splitting and ruining the boards The reason that concrete is so unusually cheap for the farmer is that he plans his forms to spoil as little lumber as possible and he finds a use for all of the lumber after it has served to hold the concrete in place In this way the material for forms costs practically nothing.

Most concrete work on the farm is built in what is known as the *box form* which with variations consists of one box within another between which the concrete walls are molded Such forms are used especially for walls of buildings tanks and troughs Ordinarily the studding need not be cut in lengths equal to the height of the wall it may without inconvenience be allowed to project above the top of the siding. Nor does it need to be sharpened (and later battered up at the other end) for driving into the ground There is a quicker easier and cheaper way Set the ends of the studding on the ground and hold them in their proper position by a timber called a *liner* lying on the ground against them or toe-nail the ends of the studding to a plate which will serve the same purpose Stakes driven into the ground and against the plates or liners will fix them firmly in place. The studding may be held plumb by bracing it with odds and ends running from the top to stakes driven into the ground a few feet away from the form. If the forms are so high and will be filled so rapidly as to render possible the springing of the studding, tie the opposite pieces together by [illegible] of bolting or other pliable wire passed through the joints in the siding Space the forms at the top by means of cross cleats

For the outside wall of box forms boards of full length need not be cut at all The extra length may be allowed to extend beyond the corners This saving cannot always be effected with the inner wall yet odd pieces of boards may often be used in such a way as to prevent useless cutting In railing on

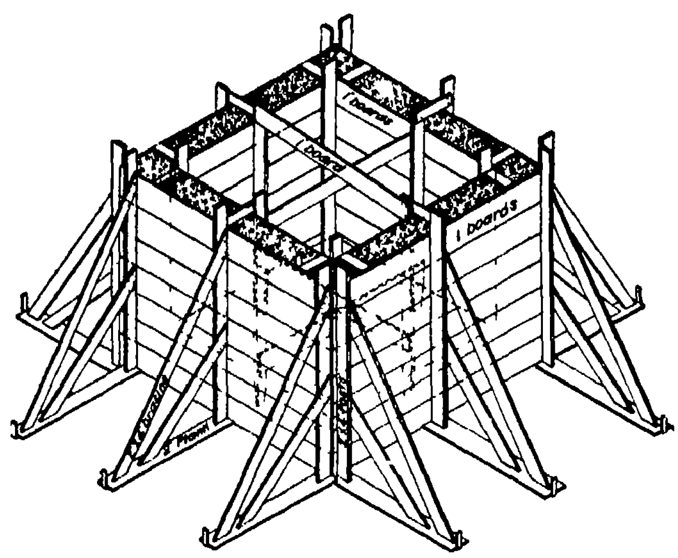


DIAGRAM SHOWING FORMS FILLED WITH CONCRETE

the siding arrange the boards so that all end joints will not be made on the same upright If the lumber is crooked draw the boards together so as to prevent cracks Since the siding is generally between the studding and the concrete heavy nailing is not needed to hold it in place until the concrete comes against it Often cleats clamps or screws are used to save the lumber and to render easier the removal of the forms The forms should always be planned with this end in view In placing the concrete avoid unnecessary lifting by leaving off a few of the boards at the top of the form until they are needed However if chips or blocks fall inside the forms carefully remove them before proceeding with the work.

See that the forms are lined up properly before beginning to fill them as they *must not* be disturbed after the concrete is in place

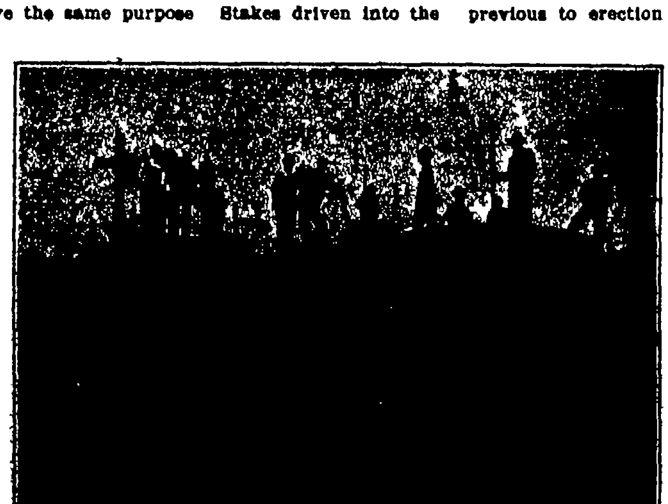
If new forms are wet, before the concrete is placed and allowed to remain in position until it has thoroughly set bits of concrete will seldom stick to them For very particular work or where forms are to be used more than once it is advisable to coat them previous to erection with soft soap or oil Linseed black, or cylinder oil is suitable but kerosene is not good Upon taking down the forms immediately clean off all bits of concrete clinging to them For this purpose a short handled hoe is convenient, but it must be used with care so as not to gouge the wood

All other things being equal the strength of concrete is dependent upon its density or compactness. Where possible, the easiest way to render concrete dense is by mixing and placing it wet. For very wet concrete the forms must be tight so that the liquid cement cannot escape To give a neat finish to the surfaces which will later be exposed force the larger stones back from the outside by running a straight spade or a wooden paddle down in the concrete next to the wall forms and working it back and forth

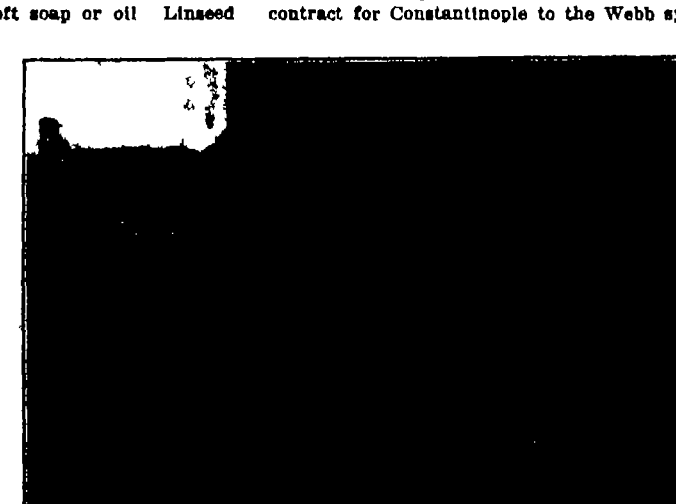
It frequently happens that very wet concrete cannot be used To make a drier mix dense and strong tamp or ram it into place with a heavy wooden or iron tamper

In a way the successful making of hay and concrete are very much alike—both must be well cured Exposed surfaces of freshly placed concrete should be shaded to protect them from rain dust, and the hot rays of the sun Freezing injures freshly placed concrete Hot water and salt are sometimes used to counteract the frost action but on the whole it is better to attempt no outside work in winter During the early months of spring and fall see that no frozen sand gravel or rock is used in the work *In summer* ordinary forms for walls supporting no loads may be removed after the concrete is three days old but *in cooler weather* they should not be touched short of five days

It is the attention to the details which makes farming or any business a success The same principle holds true of concrete work



AN ILLUSTRATION SHOWING FORMS FOR ROUND CONCRETE TANKS



VIEW OF CONCRETE FORM WITH BOARDS PROJECTING BEYOND CORNER

The Turkish government has awarded the telephone contract for Constantinople to the Webb syndicate for the space of thirty years The syndicate includes the Bell and other American interests As regards the electric lighting contract for the European quarter and suburbs the Sultan has ratified the decision awarding it to the Austro Hungarian Ganz Company backed by a strong syndicate composed of the Hungarian Bank along with French and Belgian capital. The contract figures at $4,000,000.

Balloon Signals*

An Important Aeronautic Consideration

LARGE airships have for some time been provided with wireless signaling apparatus and small air ships are now being similarly equipped Spherical balloons open below can carry wireless receivers but transmitting apparatus is excluded by its size and weight and by the somewhat questionable danger of explosion The usefulness of receiving apparatus alone hardly justifies its cost for it includes a wire several hundred yards long hanging from the car and a double wire loop surrounding the gas bag or preferably a metal plating extending over an equatorial zone or the upper half of the bag

An excellent but little used means of communication between balloons is afforded by luminous signals directed by a Morse code The same method could be employed for communicating with the earth in many cases A Nernst or other powerful incandescent electric light would be appropriate for a motorless balloon and an electric arc screened by wire gauze on the principle of the miner's safety lamp would yield a brighter light for airships The arc lamp could be operated by a small dynamo driven by the airship motor The incandescent lamp of the motorless balloon could be fed by Edison storage batteries suspended from the car in a bag and forming part of the ballast For signaling to considerable distances telescopes and parabolic mirrors or projecting lenses are required The signals can be made by opening and closing a shutter

The range of communication depends on the power of the lamp and the size and quality of the mirrors or lenses and telescopes Great distances can be attained at night and in daylight the range is at least equal to that of a Zeiss triple mirror of the same aperture Theoretically the range is four times that of a triple mirror used with the same source of light and equal to that of a triple mirror using a lamp sixteen times more powerful than the lamp employed with the system described above

The Zeiss triple mirror is a device for sending signals by the reflection of light produced at the receiving station It consists of a triangular pyramid of glass in which the three faces that meet at the vertex are mutually perpendicular like the three faces that meet at a corner of a cube The light enters the pyramid through its fourth face or base through which it also emerges after successive total reflections at the other three faces This combination of three mutually perpendicular mirrors almost exactly reverses the course of a beam of light even when the beam is not exactly normal to the base of the pyramid i e when the triple mirror is aimed only approximately at the source of light.

By means of this device, an unlighted balloon can send messages to a station which emits a steady light and conversely an unlighted station can give an immediate response to the inquiring flash of an airship's searchlight In either case the Morse code can be used by covering and uncovering the triple mirror

Variations in the position of the mirror do not affect the course of the reflected beam, unless these variations exceed the angular range within which a ray can be reflected from all three internal faces A person looking into the triple mirror sees a reflected image of his face which remains motionless when the mirror is moved turned or oscillated within its range of action Hence it is easy to obtain and maintain communication with the receiving and light-giving station

If the three reflecting surfaces are not quite perpendicular to each other the triple mirror serves also as a telemeter The effect of this construction is to divide the reflected light into two beams which diverge very slightly from each other and are seen at the receiving station to the right and left of the source of light, and separated from it by a distance proportional to the distance between the two stations

If for example, the ratio is 1 to 10 000 and it is found necessary to place the eye 12 inches to the right or left of the center of the lamp in order to see the flash of the triple mirror the distance between the two stations is 10 000 feet The range of signaling depends upon the intrinsic brightness (per unit of surface) of the source of light, and the aperture, or effective diameter of the triple mirror

The mirror here shown has a range in average atmospheric conditions of about 3 miles by day and 9 miles by night when used with a Zeiss 10-inch signal lamp These ranges can be doubled by employing an electric searchlight having four times the brightness of the signal lamp

The electric arc is the brightest of our artificial sources of light With sunlight a range of at least 37 miles could be attained but it would be necessary to throw the light upon the triple mirror by means of two very perfect plane mirrors operated by two persons as the motions of the sun and the balloon cannot be followed simultaneously with the simple army heliograph in which the two mirrors are rigidly connected

Without using sunlight the range can be extended by increasing the size of the triple mirror A 6-inch mirror would have a range of over 9 miles by day and nearly 28 miles at night A solid glass pyramid of this size would however be inconveniently heavy Hence the Zeiss firm has patented an arrangement of several triple mirrors, mounted on a board in square order and producing the effect of a single large triple mirror Such an arrangement of four triple mirrors, of 4 inches aperture, would have a range of about 12 miles by day and 37 miles at night.

A great advantage of the method of signaling with the triple mirror is its absolute secrecy for the messages cannot be received by any person except the observer standing beside the source of light. Yet any warship can throw its searchlight on a military balloon and receive secret information

Communication with scouting airships many miles in advance must be carried on by wireless telegraphy The secrecy of the messages can be assured only by an intricate cipher code as the direction of the electric rays cannot yet be satisfactorily controlled. Even the system of Losi and Bellini gives merely a greater range in one direction than in others. Disturbance by other stations and the impossibility of identifying the sender of a message are additional defects of wireless telegraphy The optical system is far superior within its limited range of 30 miles, and this range covers the most important military communications. The two systems should supplement each other

In daylight, conversation can be carried on secretly, by the Morse code between a station equipped with a searchlight and a balloon carrying a Zeiss triple mirror for the beam of light cannot be traced in the air and neither the signals sent to the balloon by intermittance of the outgoing light nor those sent from the balloon with the mirror could be interpreted by an airship which might momentarily intercept the rays in its flight At night, messages can still be sent secretly from the balloon but the secrecy of messages sent in the opposite direction may be destroyed by the visibility of the searchlight's beams (In clear weather the beam is not visible to a height much greater than 3 000 feet)

There is however a possible method of sending secret messages over a visible beam of light This method is called photophony and it involves the employment of selenium cell and other receiving apparatus which however does not weigh as much as a large triple mirror A few months ago the range attainable by this method, which was barely 5 miles was greatly increased by the invention of the telephone relay by Brown, in England It is claimed that the loudness of a telephone message is multiplied twenty fold by the insertion of one telephone relay, and four hundred fold by two relays Hence it may be expected that a practical system of communicating over great distances by means of the photophone and the telephone relay will soon be developed

* Abstract of a paper read by C von Salviati before the Aeronautical Congress in Dresden

Celebrated Echoes

ONE of the most famous echoes is that heard from the suspension bridge across the Menai Strait in Wales The sound of a blow from a hammer on one of the main piers of the structure is returned in succession from each of the cross beams that support the roadway and from the opposite pier at the distance of five hundred and seventy six feet In addition to which the sound is many times repeated between the water and the roadway at the rate of twenty-eight times in five seconds

Outside the Shipley Church in Sussex, England, is an echo that repeats twenty syllables in a most extraordinary manner The famous echo at Woodstock when awakened answers no less than fifty times

The whispering stone in Statuary Hall in the Capitol at Washington was possessed of a curious echo A person speaking in a whisper near the stone would hear his words repeated from the extreme end of the hall Reconstruction and rearrangement of the hall has changed all this to a great extent.

The echo in the castle of Simonett, about two miles from Milan in Italy repeats the report of a pistol fifty times and in the Abbey Church at St Albans in England the ticking of a watch may be heard from one end of the edifice to the other

In the Cathedral of Girgenti in Sicily the slightest whisper is carried with perfect distinctness from the western door to the cornice behind the altar a distance of two hundred and fifty feet Curiously enough, at one time the confessional was so placed that the echo of the voices of those who were confessing could sometimes be overheard by the congregation Later the confessional was removed to another part of the church.

In the whispering gallery of St. Paul's, in London, the faintest sound is faithfully conveyed from one side of the dome to the other, but cannot be heard at any intermediate point.

The Manfroni Palace at Venice possesses a square room about twenty five feet in height. It is fitted with a concave roof Standing in the center of the room a person stamping softly on the floor hears the sound repeated a great many times, but as his position deviates from the center of the floor the reflected sounds grow fainter and fainter until they die out entirely The same phenomenon occurs in the large room of the Museum at Naples

In the Gloucester Cathedral in England a gallery of an octagonal form conveys a whisper seventy five feet across the nave

The Hollow Lake region of Ontario, in Canada, is fairly alive with echoes On certain days a paddle dropped in the bottom of a canoe will sound as though several battleships were busily engaged in bombarding the place

Can a Solid be Superheated?

IT has never been found possible to superheat a solid, that is, to heat it above its melting point without melting it. Notwithstanding this negative result, some chemists, notably Ostwald, admit the possibility of superheating a solid and attribute the failure to do so to defective conditions of experiment. A Swiss scientist, A Berthoud, has lately taken up the question He shows that Ostwald's conclusions, based on a false interpretation of some experiments of Frankenheim with hydrated sodium chloride, have no justification and that Ostwald's opinion contradicts the theory, now generally admitted, which attributes retardation in change of state to the action of capillary forces.

According to this theory, if solidification, for example, does not take place, in the absence of germs, at the normal fusing point, this is because the very small solid particles which are first formed have a very large surface in proportion to their volume, and therefore possess a very great superficial energy. [illegible] formation is associated with an increase of free energy and cannot take place in the absence of such increase By adding to the supersaturated liquid a particle of the solid substance, the first phase of the transformation, which cannot take place spontaneously, is accomplished and the solidification then goes on regularly If this theory is admitted, it becomes necessary, in order to explain the impossibility of superheating a solid, to ascertain why capillary forces are not manifested in the act of fusion The reason, according to Berthoud, is that the liquid resulting from the fusion wets the solid Let us consider a piece of ice at the melting point. A drop of water placed upon the ice extends over the surface, so the boundary between ice and air is replaced by one between ice and water and one between water and air This spontaneous phenomenon is associated with a diminution of the superficial energy, instead of an increase, so that the cause which in congelation, evaporation, etc., retards the change of state, to wit, an increase of superficial energy does not exist in the case of fusion. Hence, fusion necessarily takes place, without priming, as soon as the fusing point is attained. Superheating could only take place with a solid which is not wetted by its liquid.—Revue des Science.

The production of tin-plates and terne-plates in 1909 in the United States is estimated at 612,951 tons, as compared with 537,087 tons in 1908, an increase of 75,864 tons. Of the total in 1909, 527,714 tons were tin-plates, as compared with 468,297 tons in 1908, an increase of 59,417 tons, and 85,236 tons were terne-plates, as compared with 68,[illegible] tons in 1908, an increase of 14,[illegible] tons. In addition to tin and terne plates, [illegible] lead-coated and [illegible] sheets [illegible] [illegible]

A printed copy of the specification and drawing of any patent in the foregoing list or any patent in print issued since October 4th 1859 will be furnished from this office for 10 cents provided the name and number of the patent desired and the date be given Address Munn & Co Inc 361 Broadway New York

Canadian patents may now be obtained by the inventors for any of the inventions named in the foregoing list For terms and further particulars address Munn & Co Inc 361 Broadway New York

Electrical Notes

Electric elevators for subways have not as yet been used on the Paris lines but two of the new stations are now equipped with them The stations lie on the part of the line which crosses the Seine near Notre Dame by means of a metallic caisson tunnel sunk from the surface The two stations contained in the caisson work have been opened for service quite recently and it is here that the elevators have been installed owing to the number of staircases which need to be climbed It will be some time however before the elevators are set running

Among the large steam turbine plants in Europe may be mentioned the St Denis station near Paris and there are now ten turbines in use since the late increase These are of the 100 000 size A larger one of *16 00 horse power has been added All the turbines* are coupled to dynamos At the Milan station there are now four turbines of 8 000 horse power and three others making 4 000 horse power in all In Germany the [illegible] no Westphalian Company is running two units of 10 000 horse power and five of 5 000 horse power All these turbines are of the Brown Bovert type on the Parsons principle

Much more light for a given power can be obtained from a mercury vapor lamp provided it is worked at a higher temperature than usual However the glass melts when we attempt to do this On the continent a quartz mercury lamp is now made for the purpose and it can be run at a high heat without danger of the quartz melting The light is much better and approaches a yellow hue and the glowing quartz adds red rays which improve the color It is claimed that such a lamp is as economical as a flaming arc lamp and therefore stands near the head of the list among all electric lamps It has none of the objections which make the arc more expensive on a early run on account of renewing carbons and cleaning globes

In a paper presented to the Academie des Sciences M E Salmon describes his new researches for causing reactions between bodies in the electric arc He uses an arc between tubular carbon electrodes so that the gas arrives by one tube and the products of the reaction are led off by the other The apparatus consists of a quartz tube 8 inches long closed at the ends by quartz stoppers having a 0 7 inch hole The stoppers are luted on with plaster Carbon tubes of 0 [illegible] inch diameter are held in the stoppers by asbestos sheet so that they can be slid by hand to keep up the arc The quartz tubes which are about 1½ inch diameter resist the heat of the arc very well By this arrangement the gases must pass through the arc it self before leaving at the other side which is best for the reactions He first realized some already known experiments such as combination of hydrogen and carbon to form acetylene etc The following results appear to be new He secures the direct combination of nitrogen and carbon Starting the arc for half an hour at first he then passes a current of dry nitrogen through it The resulting product was passed into a potash solution As the solution was found to give a precipitate of Prussian blue with hydrochloric acid this proved that cyanogen was formed by the arc and then absorbed by the potash to give cyanide and cyanate The direct formation of cyanogen is thus to be noted Second it is known that copper does not decompose water when at furnace heat to any appreciable extent However the heat of the arc gives a decided result Using an arc between a pair of copper tubes he collected quite a measurable amount of hydrogen in a few minutes Melted copper oxide was produced at the same time Thus he produces a decomposition of water which cannot be realized at lower heats

Science Notes

At Alise-St. Reine, France, Commandant Esperandieu discovered a small temple of hexagon form It contained a pool which was fed by a spring and this spring still exists here No doubt the water was supposed to have healing qualities seeing that votive offerings were found in the pool in the shape of images representing eyes and fingers according to the custom A number of marble busts were found on the spot Seeing that the coins which came to light here stopped at the reign of Marcus Aurelius in the year 166 A D the edifice was no doubt destroyed at that date

Dr Cartier reports to the Academie des Inscriptions as to a recent find in the North African region near Souk el Arba He uncovered a subterranean palace which was very well preserved It is of the Roman period and contains intact vaulting a Corinthian colonnade and several fine mosaics which have not as yet been all uncovered One mosaic shows a female portrait of attractive appearance while another has two Cupids mounted upon dolphins with a framing composed of a fish design He is continuing the work at present

Tunisia produces a variety of fruits which may be divided into three classes First oranges, mandarines and lemons second almonds and olives, and third orchard fruits such as peach apricot pear apple etc We also mention pomegranates and figs which are cultivated rather by the natives than by Europeans *Most of the orange crop is sold in the country and* but little is exported The almond and olive cultivation is on the increase and new plantations have been made within the last ten years Almonds are largely exported and Tunisia produces 600 000 pounds of almonds yearly exporting 400 000 pounds The present exports of dried figs are 100 000 to 140 000 pounds

M. Vournasos brings out a method for obtaining hydrogen arsenide gas by the action of formate of soda in the dry state upon arsenic and its compounds at a temperature of 400 deg C This method is not only applicable to the production of the gas but it can also be used as well as the Marsh apparatus for toxicological research for arsenic To prepare the gas the author recommend using 3 parts of arsenic in powder or arsenite of soda and 8 parts of formate of soda

CONCRETE

REINFORCED CONCRETE and CONCRETE BUILDING BLOCKS

Scientific American Supplement 1543 contains an article on Concrete by Brysson Cunningham The article clearly describes the proper composition and mixture of concrete and gives results of elaborate tests.

Scientific American Supplement 1538 gives the proportion of gravel and sand to be used in concrete

Scientific American Supplements 1567 1568, 1569 1570, and 1571 contain an elaborate discussion by Lieut Henry J Jones of the various systems of reinforcing concrete concrete construction and their applications. These articles constitute a splendid text book on the subject of reinforced concrete Nothing better has been published

Scientific American Supplement 997 contains an article by Spencer Newberry in which practical notes on the proper preparation of concrete are given

Scientific American Supplements 1568 and 1569 present a helpful account of the making of concrete blocks by Spencer Newberry

Scientific American Supplement 1534 gives a critical review of the engineering value of reinforced concrete

Scientific American Supplements 1547 and 1548 give a resume in which the various systems of reinforced concrete construction are discussed and illustrated

Scientific American Supplement 1564 contains an article *by Lewis A Hicks, in which the merits and defects of* reinforced concrete are analyzed

Scientific American Supplement 1551 contains the principles of reinforced concrete with some practical illustrations by Walter Loring Webb

Scientific American Supplement 1573 contains an article by Louis H Gibson on the principles of success in concrete block manufacture, illustrated

Scientific American Supplement 1574 discusses steel for reinforced concrete

Scientific American Supplements 1575, 1576, and 1577 contain a paper by Philip L. Wormley Jr on cement mortar and concrete their preparation and use for farm purposes The paper exhaustively discusses the making of mortar and concrete depositing of concrete facing concrete wood forms, concrete sidewalks, details of construction of reinforced concrete posts.

Each number of the Supplement costs 10 cents.

A set of papers containing all the articles above mentioned will be mailed for $1 80.

Trade Notes and Formulae

Washed clothes, bleached with chlorine (chloride of lime or bleaching powder) can with difficulty be freed from chlorine even by repeated rinsing, and if put away holes are very likely to be eaten into them If the washed linen after rinsing is passed through anti-chlorine all the chlorine will be fixed and the linen will not be injured by the bleaching Anti chlorine is prepared by dissolving 1 part of hyposulphite of soda in 10 parts of water

Water Colors.—Water colors prepared with gum or dextrine form hard solid masses that can only be softened after prolonged rubbing with the moistened brush To obtain water colors that will always be soft and can be readily taken up by the brush a solution of sugar should be used containing from 2 to 10 per cent of the weight of the sugar used of pure concentrated glycerine As the latter constantly absorbs moisture from the atmosphere colors prepared in the manner described never become perfectly hard By using thick solutions of gum to which glycerine has been added and with which the color has been rubbed down we obtain water colors which can be put up for sale like oil colors in tin capsules (tubes) and are always ready for use

The Development of Submarine Boats—II

From Bushnell to Holland and Lake

By Simon Lake

Concluded from Supplement No. 1828 page 26

The author is free to admit that there are certain mysteries connected with the control of submarine vessels in a vertical plane that are not easily explained While the problem of perfect control of such vessels in a vertical plane by the use of hydroplanes was solved on the first submerged trials of the Protector held early in 1903 at which time it was discovered that the Protector would maintain her depth automatically for considerable periods of time the importance of the exact location of the hydroplanes was not at that time fully recognized nor appreciated until the trial of the Lake in 1907 which vessel was largely a duplicate of the Protector but owing to certain overweight that crept in—primarily owing to the fact that the location of the hydroplanes had been changed from that of the relative position of the hydroplanes in the Protector —she would not submerge nor run on a level keel and it required constant manipulation of the horizontal rudder to keep her submerged When the overweight was removed and the position of the hydroplanes changed she performed satisfactorily as a level keel boat

For the purpose of observing the stream lines passing over a boat while in the submerged condition the author constructed an experimental tank in Berlin a few years ago and built models of various forms for the purpose of watching the action of the models when submerged as it was impossible to observe the stream lines if the model was pulled The tank was so constructed that the water could be driven by the model at a constant velocity by the use of propellers the velocity of the stream could be increased or diminished as desired

A model of the Protector submerged was tried out in this tank The model was free to move up or down a transverse shaft running through the model at a point half way between the centers of buoyancy and gravity wheels were fixed to the outer ends of this shaft These wheels ran up and down on vertical wires on either side of the model On the reserve buoyancy being reduced in the model to about that used in the full size boat the hydroplanes would cause the boat to submerge or emerge on a level keel in the same manner as the full size l ship It was found that with a certain inclination of hydroplane the vessel would submerge to a certain depth and automatically maintain that depth as long as the velocity of the stream was fairly uniform To go deeper required a greater angle of hydroplane or horizontal rudder Just why a vessel will submerge only to a given depth with a certain angle of hydroplane is not altogether clear At the time these tank experiments were made this fact did not impress itself on the author's mind as much as it has since due to some recent trials with one of our foreign boats which was submerged with a reserve buoyancy of about 600 pounds When first submerged it was running with an inclination down by the bow of about 1 degree The boat ran for thirty minutes maintaining a constant depth of between 31 and 32 feet without touching either the horizontal rudder or the hydroplanes It was then noticed that the boat had changed her trim for 1 degree down by the bow to 1 degree down by the stern which was gradually increasing Still the boat maintained her uniform depth A movement of 1 degree of the horizontal rudder brought her to a level keel When she showed a tendency to submerge further 2 degrees less inclination to the hydroplanes brought her back to her original depth with head of periscope about 1 foot above the surface and she ran thirty minutes more without touching anything at which time she had again taken on an inclination of about 1½ degrees down by the stern The boat was stopped and it was found that she had lost all of her reserve buoyancy except about 10 pounds and that a leaky valve had let about 600 pounds of water into the exhaust tank at the extreme after end of the boat. At rest she took an inclination of 5 degrees down by the stern

Here was a condition that had never been previously noted in the author's experience where the vessel ran at a uniform depth without touching anything during which time she changed her reserve of buoyancy and changed her trim and yet maintained a constant depth

This same phenomenon was later observed in another Lake boat where by moving men from one end of the boat to the other the trim would be changed from down by the head to down by the stern but the depth would remain constant without changing inclination of horizontal rudder or hydroplane

* Proceedings of the Engineers Club of Philadelphia.

With a certain reserve of buoyancy and a certain inclination of hydroplane therefore the vessel will always go to a corresponding depth and run constant at that depth until conditions are changed Indeed the author has heard the commander of one of these boats state for the information of the members of a trial board after first noting the vessel's reserve of buoyancy I will now set the hydroplanes at 10 degrees down and the horizontal rudder 2 degrees up and the boat will submerge to a depth of 30 feet and run constant at that depth which the vessel did without his touching anything after she started to submerge

The testing tank also showed up another curious thing A model of one of the early United States boats of the Adder type with the cigar form of hull and with quite a considerable surface buoyancy would automatically dive by the head at an angle of about 30 degrees when the bow would lightly touch the bottom of the tank and then she would reverse her inclination and come to the surface at about the same angle at which she dived At times she would reverse without touching the bottom This model had a metacentric height corresponding to about 10 inches in a full-sized ship It was very interesting to observe this porpoise like motion which kept up continuously as long as the stream was flowing and it was impossible to set the horizontal rudder in any position to overcome this tendency The porpoising motion was so rapid that it was impossible to get any accurate observation of the stream lines but it is believed that the explanation is much the same as of the hydroplane action viz as the vessel gathers headway the water piles up over the cigar-shaped bow which combined with the increased frictional resistance due to the streams passing under the hull causes the bow to submerge and the vessel plunges toward the bottom A cross section parallel to the surface through the hull near the bow as she is diving would show if she was moving forward at the same time) that there would be a tendency to create a vacuum under the forward portion of the vessel which would tend to increase the inclination and she would continue to dive until a sufficient inclination and depth was reached whereby the greater head of water at the bow reduced the vacuum and consequent down pull on the bow and at the same time the vacuum formed under the stern was proportionately increased which combined with the righting effect of the pendulum arm (her metacentric height) caused the forces to be reversed and she would broach to the surface The motion of the model would apparently synchronize and the plunge toward the bottom and return to the surface again would occur with the regularity of clockwork The obvious remedy for this tendency in a boat of the cigar shaped form is to increase the metacentric height and the size of the control rudders and to keep in constant touch with the horizontal rudder

The above theory may explain the fatal dives to the bottom of some of the vessels of the diving type

One of the advantages of bottom wheels in surmounting obstructions is in running in waters not well charted where it is assumed that there are several fathoms of water the keel striking and surmounting obstructions of unknown objects The cushioning wheels take up the shock and the vessel surmounts the obstruction without the hull coming in contact with the object

Speed as every engineer knows is simply a question of lines and horse power The author has always felt that safety and ease of control should be the first consideration in the design of submarines The submarine does not require great speed especially under water The submarine is the guerilla in warfare and it is her province to lie in wait for her fleeter foe the armored cruiser or the battleship For preventing a close blockade of a port a very slow submarine would have frequent opportunity to intercept a blockading squadron. Speed is now becoming more desirable, however as the submarine is going to take the offensive in naval warfare rather than the purely defensive position to which these vessels have been considered adaptable

In the author's opinion the proper method of making a submarine attack is for the submarine to run on a level keel a sufficient distance below the surface so that when the omniscope and periscope are withdrawn there is absolutely nothing on the surface to betray the fact that a submarine is in the vicinity.

The vessel which carries six of the deadly Whitehead torpedoes, all of which may be almost simultaneously fired two at the bow two at the stern, and two to either broadside. The periscope is kept housed except at the moment of taking an observation Range-finding and direction indicating devices are provided by means of which the navigator of the submarine may be constantly advised as to the position of the enemy Observations may be made by suddenly shooting the head of the periscope just slightly above the surface and as rapidly withdrawing it An observation may be taken and the distance of a known ship calculated in a space of time not exceeding two or three seconds during which period no gun could be trained on so small an object as the head of a periscope even if it was observed which in a choppy sea is hardly likely even at a distance of only 300 or 400 yards and at a distance of a couple of thousand yards would be invisible even with a very powerful glass provided the vessel did not have sufficient speed and the periscope did not remain above the surface long enough to create a wake It is the wake of the periscope which attracts attention to a vessel running with the periscope above the surface all the time

DISCUSSION

In reply to questions by members Mr Lake stated as follows

All of the French boats so far have been built in France and all of the recent French designs have been made by French officers He thinks that Goubet the designer of a little French boat shown experimented privately The United States Government has furnished no designs Its latest call for tenders distinctly states that the Government has no designs

Reference was made to what is known as the Board on Construction which has been discontinued There is now a General Board of which Admiral Dewey is the head The Board on Construction was composed of the heads of the Bureau of Construction the Chief of the Ordnance Bureau the Bureau of Engineering the Bureau of Equipment and the Chief Intelligence Officer These men would get together and decide on all classes of ships except submarines which class was formerly decided upon only by Congress The Naval Board formerly had nothing to do with this due to the wording of the legislation Now however it does and the Department issues circulars to ship builders and specifies what it wants in the way of armament and performance Since the United States has the advantage of getting competitive bids the requirements are as severe as if not more so than those of any foreign government.

The difference between a horizontal rudder and a hydroplane is this A horizontal rudder is placed at the bow of the boat or at the stern and has simply a guiding function to direct the course of the vessel up or down The hydroplanes pull the boat up or down bodily as it were In the Lake type of boat they have always been equally distributed one an equal distance forward and another an equal distance aft of the center of gravity so that the forces acting upon them tend to force the boat down bodily on a level keel and they also lift the boat on a level keel With a horizontal rudder one must change the whole angle of the boat itself, while with the hydroplanes one instantly gets down pull or up pull.

Air is compressed in steel bottles Under the present government requirements all submarines must provide for a certain number of cubic feet of air up to as much as 2,500 pounds per square inch. The United States Government made a number of trials in 1907 in which the "Fulton and the Lake both remained submerged for a period of twenty-four hours Mr Lake had previously made experiments in 1897 to determine how long a crew could remain submerged living on air in the boat alone without drawing in an outside supply. The Argonaut was only 36 feet long and was for a period of five hours submerged without drawing on any air-supply from outside. Eight men at Newport in the 'Lake' remained for twenty hours under water without drawing on outside air, at the expiration of which time the air was getting a little thick and Mr Lake noticed that some of the men were losing interest in things about them. He had been observing the condition of the air by watching a lighted candle, measuring the height of the flame of the candle both at the top and at the bottom of the boat. In this way he could judge if carbonic acid gas was forming. He would repeat this test every hour, and after they had been submerged fifteen or sixteen hours he noticed that the flame began to diminish, which was the first indication of bad air. At the end of twenty hours it was impossible to keep the candle

[illegible]. About that time the men began to get sleepy and to breathe rather heavily; some fresh air was then admitted from the storage bottles The pumps were started and pumped the foul air out from the bottom of the compartment and the fresh air was admitted at the top; the candle flame then immediately brightened. They then remained for two hours longer, until the candle flame began to show signs of getting weak again, when they repeated the pumping operation and remained for another two hours and so on. When they came to the surface they immediately got under way and went back to Newport and none of the men suffered any bad effects

Boats have electric heaters and cooking is done with electric apparatus, the crew lives aboard some of the boats altogether

The French Government has been the most industrious in trying to use heavy oils for fuel for engines in fact, abroad a number of Continental firms have been experimenting with the Diesel engine and have met with considerable success within the last few years One government has proposed changing its gasoline engines for heavy oil engines so well was it satisfied with their performance Alcohol has not the same power as gasoline When one attempts to provide a fuel which reduces power and speed governments do not want it, so it looks as if the heavy oil engine is the solution of the problem Heavy oil engines are now so successful that Mr Lake proposes putting them in his future boats but he has never felt warranted in doing so heretofore

Compressed air is not carried in submarines for the sole purpose of providing air for the crew but for the purpose of handling water ballast discharging torpedoes and working certain machines. The Whitehead torpedo is discharged by compressed air

All of our boats are provided with a buoy which may be released to the surface The Russian buoy has information printed upon it in three languages English Swedish and Russian notifying the finders that there is a submarine boat below and asking them to open the buoy When one does so a telephone is found inside by means of which one can talk to the boat below There is a whistle on these buoys which is blown by compressed air and a light can be turned on at night they also have a tube by which the boat can be supplied with fresh air

Mr Lake knows of no practical method for vessels to protect themselves against submarines that has been proposed The putting out of booms he considers would be no defence at all because it would reduce the speed of the surface vessel using it The only protection vessels have to day against submarines is to get into a landlocked harbor and then have the harbor closed after them The putting out of booms and heavy chain netting would not assist them because their speed would be reduced so that the submarine could approach them at will and go under the chain if necessary or fire a succession of torpedoes and destroy the booms The only safety for the pursued vessel is to put out to sea and get away if she knows a submarine is below The torpedo will put any ship out of business and a submarine can approach any ship to-day The next war will without doubt prove that these little Davids are invincible

The British Government has made experiments exploding gun-cotton and found that an explosion 20 feet away from the vessel would do her no serious injury but an amount of gun-cotton exploded directly beneath a ship even at 100 feet depth would Mr Lake believes that a submarine would not be injured unless a mine were exploded right under her at a distance of 50 feet, it would not even rupture the hull

The best speed for submarines as far as Mr Lake knows is between 15 and 16 knots on the surface with gasoline engines He thinks that will be increased considerably within the next few years

Submarines are now built which have a submerged speed of 11 knots and this will also probably be increased

Mr Lake has made experiments and has kept the hair lines of the omniscope (which by means of direction indicating devices aims the torpedo) pointed right on the stem of a vessel for a period of as much as five minutes at a time that was actually done while a vessel was passing at a good rate of speed The man at the observing instrument can check on his hair lines and certain measuring devices the course of the vessel and correct the same The difficulty is will the torpedo run straight? Torpedoes are now made that will run up to 4 000 yards

Mr Leavitt who is the inventor of the torpedo of that name suggests that it might pay with torpedoes used by submarines to increase the charge of gun cotton and reduce the run Mr Leavitt sees no necessity for torpedoes which run over a thousand yards to be fired from submarines Of course when one fires at 4 000 yards the chances for making a hit are much decreased

Vanadium—Its Discovery and History

Found in a Brown Lead Ore from Zimapan, Mexico

In a formal communication dated at the city of Mexico on the second of the month Messidor in the ninth year of the French Republic Humboldt and Bompland first announced the discovery of the metallic element vanadium to the National Institute of France

The date given corresponds to the 21st day of June 1802 but the notice of the discovery was not published until 1804 when it was inserted in the Annals of the National Museum of Natural History

The discoverer of the new element was Manuel Del Rio Professor of Mineralogy in the city of Mexico He found it in a brown lead ore from Zimapan and after noting that it was different from chromium and uranium, called it erithronium because of the red color of its salts

In May 1803 or before Humboldt s letter to the French Institute was published there is an obvious reference to vanadium under the name of panchrome the article appearing in Spanish in the Annals de Ciencias Naturales and Del Rio being credited with the discovery of the substance

Humboldt together with his letter concerning erithronium sent to France samples of the brown mineral in which it had been found Collet Descostils an engineer in the Corps of Mines already known for his work on platinum and his reputed discovery of rhodium was entrusted with the analysis of the Mexican ores. His report was negative in reference to erithronium and concludes with the statement that the tests which he had made seemed sufficient to prove that these ores did not contain any new metal

Before he learned of the results of Collet Descostils s analyses and even before the announcement of his discovery had reached France, Del Rio changed his opinion and regarded erithronium (or panchrome) simply as a basic chromate of lead Writing on the lead minerals from the district of Zimapan he states

"From this brown lead ore I have extracted 14 80 per cent of a metal which at first seemed a new one and which I called panchrome because of the different colors presented by its oxides, its solutions and its precipitates, then I named it erithronium because it formed with alkalies and earths certain salts which became red under the action of heat and acids But having read in Fourcroy that chromic acid also furnishes red and yellow salts by evaporation I concluded that the brown lead ores were chromates of lead with an excess of base in the state of a yellow oxide Until the present, it has been regarded as a phosphate of lead."

Del Rio thinking that he had made a deeper study of the minerals, thus concluded that he had made an error in his first report, and he gives the result of his subsequent analysis of the lead ores as follows

"The brown lead mine contains 80 72 per cent yellow oxide of lead, and 14.80 per cent of chromic acid, the [illegible] per cent consists of arsenic, iron oxide and [illegible] acid."

[illegible] and erithronium, renounced by their discoverer [illegible] by an eminent French chemist were then forgotten and never entered the list of the chemical elements

More than a quarter of a century later in November 1830 Berzelius writes the following letter to Dulong

M Sefström director of the School of Mines of Fahlun on examining a piece of iron remarkable for its extreme softness has just recognized in it the presence of a substance of which the properties differ from those of all the elements known up to this time but the proportions of this substance are so small that it will require much time and expense to obtain a quantity sufficient for a thorough examination The iron comes from the mines of Taberg in Smaland the ores of which also contain traces of the new substance M Sefström having discovered that the pig iron contained a larger proportion of the substance than the iron refined therefrom concluded that the slags formed during the conversion of the pig iron into refined iron would be still more rich this conjecture was soon confirmed and M Sefström having thus succeeded in procuring a sufficient quantity of the new substance to enable him to study it came to me during the holiday vacation to finish his researches on the subject

Sefstrom after many experiments on the Taberg irons applied himself to studying the characteristic reactions of the new element and to marking the distinctions between it and chromium and uranium both of which metals exhibited many analogies The result was that with only two decigrammes of material to work upon he established the existence of the new element beyond question He recognized its several degrees of oxidation and even described some of its salts

Taking up his researches again in the autumn of 1830 at Fahlun, in the laboratory of Berzelius, he succeeded in extracting further quantities of the new element from furnace slags indicated his method of recovering it and named it vanadium from Freya Vanadis, the principal goddess of Scandinavian mythology

Hidden in the earth since time began suspected for thirty years and then conclusively recognized vanadium thus took its place among the elements in the year 1830

Berzelius, in his communication to the Annales de Chimie et de Physique credits Sefström with the discovery of vanadium gives the result of his researches and commends him for his success in overcoming unusual difficulties

Berzelius then endeavored to isolate the metal but failed Attempting to reduce the oxides by carbon and by hydrogen he obtained in both cases only a lower oxide with a somewhat metallic luster Using potassium, he obtained a grayish powder which gave a metallic luster when polished He then heated vanadium chloride in a current of dry ammonium gas and produced a compound with a brilliant metallic luster but which Schafarick proved was only the nitride of vanadium.

Johnson, Crudnowiez, Rammelsberg and Schabus continued the work on vanadium and without isolating it succeeded in fixing its classification in the system of elements

Sefstrom had found vanadium in iron ores other than those of Taberg Kersten found it in 1841 in the copper schists of Mansfield and Thuringia Woehler discovered it in the pitchblend of Joachimsthal now so famous on account of its radio-active elements But in none of these cases did the vanadium content run higher than one tenth of one per cent and the combinations made by the metal remained undetermined No industrial application had been found for it and its detection in widely scattered localities was simply a matter of chance

In 1859 H St Claire Deville sent a note to the Academy of Sciences and indicated the presence of considerable quantities of vanadium in a ferruginous aluminium deposit at Baux between Arles and Toulon

About this time vanadium was discovered in many kinds of clay throughout France Terrell found it in some Sevres pottery but in very small quantities

St Claire Deville suggested the first industrial application of vanadium as a coloring agent in ceramics He also prophesied its larger employment in metallurgy after noting the improvement in some cast iron that showed the presence of vanadium

Commercial caustic soda and potash usually contain vanadium sulfide of sodium even the purest kind always presents a slight yellowish tinge due perhaps to traces of vanadium Roscoe found it in 1867 in the copper deposits of Cheshire England Witz and Osmond found it in the basic slags from the Creusot furnaces in which the oolithic ores of Mazenay were used the quantity rising as high as one per cent This vanadium was used exclusively in the manufacture of aniline black because of its powerful oxidizing properties

Vanadium exists in considerable quantities in the oils and anthracites of South America and is found in the titaniferous iron ores of the Adirondacks It has been found in meteors and exists in some stars and the sun

Sir Henry Roscoe isolated it in the metallic form in 1867 Moissan made cast vanadium in the electric furnace in 1894 Helouis developed a commercial process for the preparation of vanadic acid in 1896 and produced in the same year alloys of vanadium and iron by the alumino-thermic process

Electric traction matters are very active in the Pyrenees region of France About 200 miles of standard gage road will be equipped by the South Railroad Company from Bayonne to Toulouse The work will be started with the 65-mile section between Montrejeau and Pau For this thirty motor cars have already been ordered, and they will take 100 ton passenger trains. On this line the single phase 300-volt system will be used The company is taking steps to erect these hydraulic plants in the mountain region to secure the current.

Experimental Science Teaching

Some Applications of Mariotte's Bottle

The apparatus known as Mariotte's bottle consists in its simplest form of a half gallon or gallon bottle (*A* in Fig 2) having a horizontal outlet tube near its bottom and a vertical tube which passes through a cork into the neck and extends inside the bottle to any desired level higher than the lateral outlet. When the bottle is filled with water and the outlet is opened air enters in bubbles through the vertical tube and water flows from the outlet in a stream of constant velocity as long as the level of the water in the bottle is higher than the bottom of the vertical tube because in these conditions the effective head of water that determines the flow is the height of the bottom of the air tube above the outlet no matter what the actual level of the surface of the water in the bottle may be. Mariotte's bottle therefore affords a convenient means of obtaining a steady and uniform flow of water and it is for this purpose that it is employed in the experiments here described.

Intermittent Springs.—The action of natural intermittent springs of water may be illustrated and imitated by means of the Mariotte's bottle in conjunction with the toy called the vase of Tantalus which is shown at *D* in Fig 2. The vase of Tantalus is a vase or jar the bottom of which is traversed by a tube having both ends open and the upper end bent downward to form a siphon. It easily can be

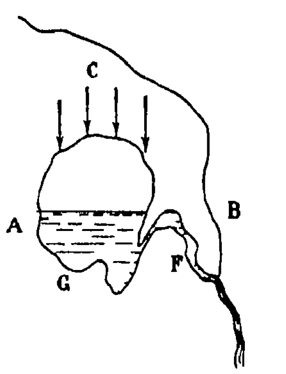

Fig 1.—Natural Intermittent Spring

made at home by fitting a cork to a hole cut in the bottom of a tin pail or biscuit box and fitting to a hole bored in the cork a glass or rubber tube bent to the required form as is shown in the right hand illustration of Fig 2 where *E* is the pail or box and *F* the tube. The left hand illustration shows the conventional vase of Tantalus arranged in combination with a Mariotte's bottle to imitate the action of an intermittent spring. The Mariotte's bottle *A* placed on a high support *C* discharges through its outlet *B* a constant stream of water into the vase of Tantalus *D* which is placed on a lower support *C*. The water cannot escape from the vase of Tantalus until it has risen to the top of the siphon *F*. It will then begin to flow out through the siphon into the vessel *G* beneath and it will continue to flow until the level of the water in the vase has fallen to the level

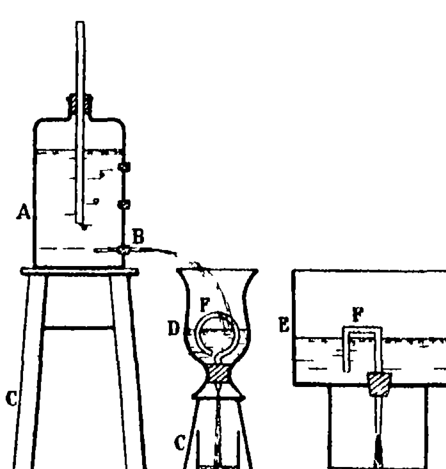

Fig 2.—Artificial Intermittent Spring

of the mouth of the siphon. The flow from the vase of Tantalus will then stop but it will recommence when the water level in the vase has again been raised to the bend of the siphon by the constant inflow from the Mariotte's bottle. With a siphon of large bore combined with a small outlet and low head of water in the Mariotte's bottle the water will escape in sudden gushes at considerable intervals from the vase into which it is slowly and steadily trickling from the bottle. The action of a natural intermittent spring is quite analogous to this. The spring is the outlet of a natural fissure *F* (Fig 1) having the form of a siphon and communicating with a cavity *G* into which water slowly percolates as is indicated by the arrows *C*. When the water attains

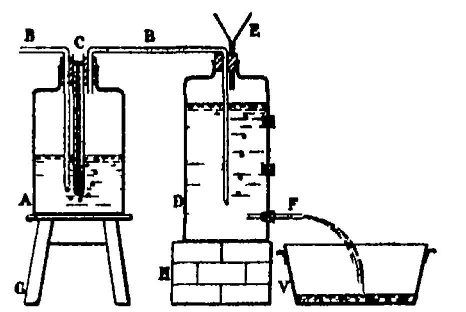

Fig 3.—Cooling and Freezing Water

the level *AB* a large quantity is rapidly discharged and the spring then ceases flowing until the water level has again been raised to *AB* by infiltration.

Cooling and Freezing Water.—Half fill with ether a wide mouthed bottle *A* (Fig 3) and fit to holes bored in the cork two bent glass tubes *BB* and a test tube *C* containing water and a thermometer. One of the bent tubes *B* dips into the ether and its upper end communicates with the atmosphere. The other tube *B* extends only a little below the cork and is connected with the air tube of a Mariotte's bottle *D* which is filled with water and has a large outlet *F* closed by a cork. The height of the thermometer is noted and the cork is removed from the outlet of the Mariotte's bottle which acts as an aspirator and draws a current of air through the tubes *BB* and the ether in the bottle *A*. The rapid evaporation of ether thus caused produces a correspondingly rapid lowering of the temperature of the water in the test tube which is soon cooled to the freezing point if the air of the

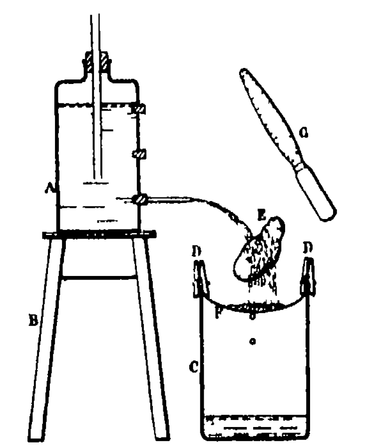

Fig 4.—Analysis of Potatoes and Flour

room is moderately cool. In order to freeze the water however the Mariotte's bottle must be refilled two or three times and the flow quickly re-established. Time can be saved by providing the Mariotte's bottle with a funnel *E*. This experiment illustrates the method of cooling and making ice by the evaporation of liquefied ammonia and other gases.

Analysis of Potatoes and Flour.—Fig 4 illustrates the use of a Mariotte's bottle in separating the starch from potatoes. The peeled potato *F* is rasped with the rasp *G* under the stream of water issuing from the tapered outlet *H* of the Mariotte's bottle *A* and over a piece of muslin *F* fastened by spring clips *DD* to the rim of a deep vessel *C*. The broken starch cells consisting chiefly of cellulose, are retained by the cloth while the starch and water pass through. The starch grains slowly settle to the bottom of the vessel *C*. The water is then decanted and the wet starch is dried on a surface of plaster of Paris. Flour is analysed by kneading it with the hand under the jet of water which carries the starch into the receiving vessel while the gluten remains as a plastic mass in the hand.

Cooling Laboratory Distilling Apparatus.—Fig 5 shows a Bunsen burner *F* heating a retort *A* of which the neck *B* enters that of a receiver *C* which is cooled by a stream of water from a Mariotte's bottle *E*.

Cooling Woolf Bottles, Etc.—A Woolf bottle is a bottle with three necks which is used in preparing solutions of ammonia and other gases. In many cases continuous refrigeration of the apparatus is necessary. For this purpose a Mariotte's bottle filled with cold water may be employed, in the manner shown in Fig 6. The Woolf bottle *A* contains water in which gaseous ammonia, flowing in through the left hand tube *B* to the bottom of the vessel is being dissolved while any excess of gas escapes through the right hand tube *B* to a second Woolf bottle (not shown). *C* is a safety tube which by admitting air prevents the pressure in the space above the liquid from falling low enough to cause an influx of liquid from the second bottle. The Woolf bottle pictured stands in a vessel filled with cold water which is frequently or continually replenished by means of the funnel *F* and the Mariotte's bottle *M* while the uppermost and warmest stratum flows off through the outlet *G* to the vessel *R*.—La Science XXme Siècle.

Inheritance of Acquired Characters

In the Scientific American Supplement early in 1910 there appeared an account of some experiments by Dr Paul Kammerer of Vienna wherein the amount and distribution of pigment in the skin of certain lizards was modified by the conditions under which they were kept and these modified patterns were reproduced in the offspring kept under normal conditions.

Dr Kammerer has been continuing his experiments with lizards and reported some further results at

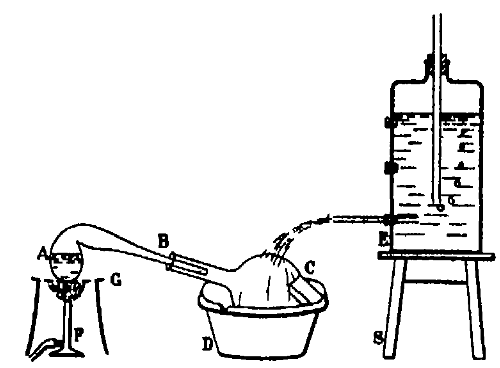

Fig 5.—Cooling Receiver of Retort

the International Physiological Congress held in Vienna this fall.

In the first series of experiments the modifications produced were in the reproduction of the animals. *Lacerta vivipara* instead of laying eggs like the other members of the genus bears its young ready formed. A number of these animals were kept in a warm chamber—25 deg to 30 deg C.—and these laid eggs which afterward hatched out. The first batch of eggs laid were without shells the later batches had parchment like shells resembling those of other species that normally lay eggs. A species that bears young was there modified by the temperature into one that bears eggs. The lizards that hatched from these eggs were placed in chambers of normal temperature here instead of reproducing by bearing young as we should expect according to the prevailing biological theories the females laid eggs again. Here then there appears to be a transmission to the offspring of a modification induced in the parents.

Another experiment was conducted with specimens of *Lacerta serpa*, which normally lays eggs with a soft shell. On keeping these in a warm room—30 deg to 35 deg C.—the later eggs were found to have

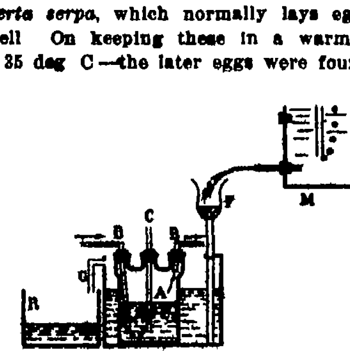

Fig 6.—Cooling Woolf Bottles

rather hard shells. The lizards that hatched out of these eggs were kept at normal temperatures but when they reproduced, their eggs were provided with the hard shells. Again there seems to be the transmission of a character that was acquired during the lifetime of the parent as a result of the action of some external factor.

The other experiments had to do with the modification of colors by increase in temperature, and were similar in their results to those already described in the article referred to.

Magnetic Crystals

An Interesting Investigation Into the Magnetic Properties of Crystals

By Dr Victor Quittner

STRICTLY speaking, crystal magnetism is the oldest part of the entire subject of magnetism for magnetite, lodestone or magnetic iron ore which crystallizes in beautiful octohedra and rhombic dodecahedra is the substance in which the phenomena of magnetism were first observed by the Greeks After a method had been discovered of making steel magnets very much stronger than natural magnets the latter lost their practical importance and no further attention was paid to them For centuries magnetic observations were confined to iron which was regarded as the only magnetic substance

In 1845 Faraday discovered that all substances without exception possess magnetic properties generally however to so slight a degree that the most delicate instruments are required for their detection Substances are divided into two classes paramagnetic substances which are attracted by both poles of a magnet, and diamagnetic substances which are repelled by both poles Both attraction and repulsion are produced by the magnetization of the body by the external magnetic field When a paramagnetic body is placed between the poles of a powerful magnet a south pole is developed in the body opposite the north pole of the magnet and conversely As each of these induced poles is of opposite sign to the pole of the strong magnet which is nearest to it the body is

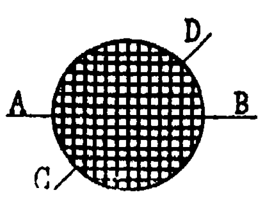

Fig 1 Grating of Iron Wires representing Plate cut from a Crystal of Magnetite

attracted by both poles of the magnet When a diamagnetic body is placed between the poles of a strong magnet a north pole is developed opposite the north pole of the magnet and a south pole opposite the south pole Hence the body is repelled by both poles of the magnet The results may be expressed by saying that in paramagnetic substances the magnetization and the external field have the same direction but in paramagnetic substances their directions are opposite

A special class of paramagnetic substances which are attracted very strongly by magnets are called ferromagnetic Only six such substances are known 1 iron in all of its modifications 2 nickel 3 cobalt 4 magnetite or lodestone 5 magnetic pyrites ($Fe_7 S_8$) also called pyrrhotin 6 the magnetic alloys of copper manganese and aluminium which were discovered by Heusler a few years ago In a field of given strength ferromagnetic bodies acquire a magnetization millions of times stronger than that of ordinary paramagnetic and diamagnetic substances and they also show many other peculiarities which warrant their segregation in a special class One of these peculiarities is their behavior in fields of different strengths In paramagnetic and diamagnetic bodies the magnetization is simply proportional to the strength of the external field up to the strongest

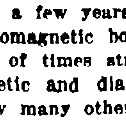

Fig 2 —Arrangement of Molecules in Magnetite

fields that can be produced (46 000 gauss) In ferromagnetic bodies this proportionality holds only in very weak fields (less than one gauss) As the strength of the field increases the magnetization increases also but less rapidly until with a field of 1 000 to 3 000 gauss the magnetization attains a limit beyond which it cannot be increased by increasing the strength of the field This condition is called magnetic saturation Another peculiarity of ferromagnetic bodies, called hysteresis consists in their consumption of energy and its transformation into heat when their magnetization is repeatedly and rapidly reversed Probably paramagnetic bodies would exhibit the same property in fields of several million gauss but such fields cannot be produced

To return to magnetic crystals. All crystals may be regarded as magnetic, for every crystal, like every other body, is either paramagnetic or diamagnetic or ferromagnetic.

The extensive researches of Plücker and Faraday proved that the magnetic phenomena of crystals differ from those of other bodies If a sphere of an uncrystallized or isotropic substance is placed in a uniform magnetic field it remains in equilibrium in any position But a sphere of calc spar for example placed in the same field turns so that its principal crystal

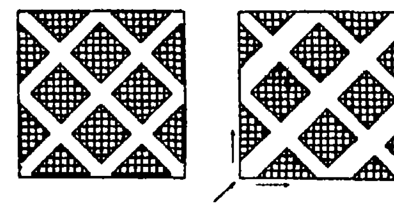

Fig 3 —Effect of Fissures in Magnetite

lographic axis is perpendicular to the lines of magnetic force Diamagnetic crystals of antimony and paramagnetic crystals of tourmaline beryl etc behave like the diamagnetic crystals of calc spar Other crystals including those of bismuth arsenic and zirconium (diamagnetic) spathic iron ore and uranium mica (paramagnetic) place themselves with the principal crystallographic axis parallel to the lines of force The phenomena vary greatly with the different crystalline systems Faraday was unable to explain them otherwise than by the assumption of a peculiar force which he called magne crystallic force This was no explanation but only the invention of a name

A real theory of crystal magnetism which explains the apparently very complicated phenomena in an exceedingly simple manner was devised a few years later by Sir William Thomson (Lord Kelvin) I will attempt to present this theory in an easily intelligible form

In every crystal and in every anisotropic body in general there are three special directions which are called magnetic axes When the crystal is placed in a magnetic field with any of its axes parallel to the lines of force it behaves like an isotropic body i e it acquires a magnetization (para or dia) in the common direction of that axis and the field If this experiment is repeated with each of the three axes suc

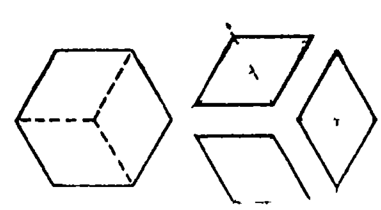

Fig 4 —Hexagon Composed of Three Rhombs

cessively parallel to the lines of force it is found that a field of given strength produces different degrees of magnetism in the three cases Phenomena of very different character are exhibited when the axes are inclined to the magnetic field In this case the axis along which the strongest magnetization can be produced draws so to speak the magnetization to itself so that the direction of magnetization within the crystal is intermediate between this axis and the direction of the field Consequently the crystal turns and continues turning until the axis of greatest magnetic permeability that is the axis along which the strongest magnetization can be produced is parallel with the lines of force If the crystal is diamagnetic the result is similar but in the final position of the crystal the axis of least magnetic permeability is parallel to the lines of force In these experiments it is assumed that spheres or disks cut from the crystals are employed as otherwise the position may be modified by the form of the body

Thomson's theory gives a qualitative and quantitative explanation of all the phenomena observed in paramagnetic and diamagnetic crystals It makes the assumption of any special force unnecessary so that Faraday's magne-crystallic force has disappeared from the text books This theory also makes it possible to deduce the magnetic properties of a substance from its crystalline form

There are six fundamental systems of crystallization 1 regular or tesseral 2 quadratic or tetragonal 3 hexagonal 4 rhombic 5, monoclinic and 6 triclinic or unsymmetrical From everything that we know of the other physical properties of crystals we should expect their magnetic properties to exhibit the same variety of symmetry that is shown by their crystalline structure. In the regular system, in which the three principal axes of crystallization are identical in every respect we should expect the three principal magnetic axes which coincide with the crystallographic axes to exhibit equal capacities for magnetization But if this is the case the direction of magnetization in any position of the crystal must coincide with the direction of the external magnetic force and the crystal must behave in the magnetic field exactly like an isotropic or uncrystallized substance We shall see later that this is not quite true in the case of ferromagnetic crystals of the regular system Crystals of the tetragonal system have one principal axis and two or three secondary axes lying in a plane perpendicular to the principal axis In this plane the crystal acts as an isotropic body as the secondary axes are entirely similar to each other According as the principal axis is more or less magnetisable than the secondary axes and according as the crystal is paramagnetic or diamagnetic it places itself with the principal axis in the direction of the magnetic field or perpendicular thereto In crystals of the rhombic monoclinic and triclinic systems there are three magnetic axes of unequal permeability which coincide with the crystallographic axes only in the rhombic system The crystal if paramagnetic places itself with the axis of greatest permeability in the direction of the field

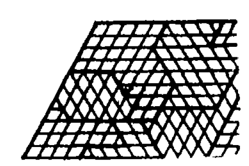

Fig 5 —Arrangement of Elementary Rhombic Crystals in Pyrrhotin

if diamagnetic with the axis of least permeability in that direction The following table gives the above mentioned facts at a glance

Paramagnetic and Diamagnetic Crystals

Crystalline System	Magnetic Properties.
Uncrystallized Regular	3 equal magnetic axes Isotropic in all directions
Tetragonal Hexagonal	3 magnetic axes only two of which are equal Isotropic in the plane of these axes which is perpendicular to the third or principal axis
Rhombic Monoclinic Triclinic	3 unequal magnetic axes Anisotropic in all directions

For many years Thomson's theory comprised our entire knowledge of the magnetic properties of crystals and it was generally believed that the theory applied to all crystals including those of ferromagnetic substances of which no exact studies had been made

Our knowledge of the properties of ferromagnetic crystals are due entirely to the researches of Prof

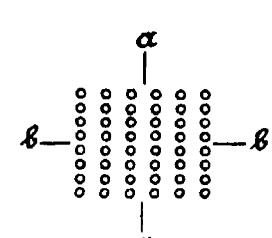

Fig 6 Arrangement of Molecules in Pyrrhotin

Pierre Weiss of Zurich and his pupils of whom the writer of this article was one The researches were not undertaken solely with the view of exploring this very small field but especially for the purpose of affording a basis for a theory of the very incompletely known and understood properties of iron and other ferromagnetic substances for all strongly magnetic substances are composed of microscopic crystals It seemed probable that a single crystal possesses properties of simpler character than those of the mass and that when the properties of the elementary crystals had been determined it would not be difficult to calculate those of the mixture of crystals which constitutes the apparently isotropic ferromagnetic substance.

The experiments were conducted chiefly with crystals of magnetite and pyrrhotin also with small crystals of metallic iron which are occasionally found in

old railway rails and in iron manufactured by Goldschmidt's thermite process These crystals of iron are never larger than a few millimeters and are consequently too small for exact measurements but magnetite and pyrrhotin occur in fine large crystals Magnetite chemically an oxide of the formula Fe_3O_4 crystallizes in the regular system forming octohedra and rhombic dodecahedra some of which are four inches in length Pyrrhotin is a sulphide which contains from 36 to 39 per cent of sulphur corresponding approximately to the formula Fe_7S_8 or Fe_8S_9 It crystallizes in hexagonal pyramids and prisms belonging to the hexagonal system Metallic iron crystallizes in small cubes belonging to the regular system In some of the experiments the substances were employed in the form of small rods but they were more generally used in the form of thin plates cut from the crystals in various directions The diameters of the plates ranged from 1/2 inch to 4/5 inch according to the size of the crystals Only the larger plates could be employed for exact measurements Very great importance was attached to having the plates perfectly circular and of uniform thickness throughout hence very great care was ta[illegible] oduction Because of their fragility they were cemented to glass plates with Canada balsam and cover glasses were fastened over them

A detailed description of the experiments and measurements would necessarily be too technical to have general interest I will merely mention that two general methods were employed In one the crystal plate was suspended in a horizontal position between the poles of a magnet and the force with which the external magnetic field turned the plate was measured by the torsion of a spiral spring by which the plate was suspended In the other method a galvanometer was employed to measure the current induced in a coil of wire when the magnetized crystal plate was inserted in the coil The results obtained by the two methods always agreed very closely The first experiments the results of which were published in 1896 related to magnetite Considerable surprise was created by the discovery that magnetite although perfectly regular in crystalline form does not behave like an isotropic substance in the magnetic field Upon a little consideration however this result does not appear so surprising for Thomson's theory is based upon the assumption that although the magnetization of a crystal may be unequal in different directions it is in each direction proportional to the intensity of the field We have already stated that although this law is obeyed perfectly (at least with any strength of field that we can produce) by diamagnetic and ordinary paramagnetic bodies it is not obeyed by ferromagnetic substances either isotropic or crystallized

Hence Thomson's theory does not apply to ferromagnetic crystals and the conclusions drawn from this theory with regard to the magnetic behavior of crystals of the regular system do not hold in the case of ferromagnetic substances When a plate of magnetite cut perpendicular to any one of the crystallographic axes was placed in a weak magnetic field (31 5 gauss) it appeared perfectly isotropic but when the strength of the field was increased the magnetization in the direction of either axis was found to be much smaller than the magnetization in a diagonal direction When however the strength of the field was still further increased this difference gradually disappeared until with a field of 1 000 gauss the magnetization became equal in all directions and attained its maximum or saturation value of 482 magnetic units The limit of saturation of good wrought iron is 1750 Hence the magnetic capacity of magnetite is 3 6 times less than that of soft iron and nearly equal to that of nickel (490)

How can these phenomena be explained? Let us suppose that the crystal is composed of a framework of iron wires one third of which run parallel to each of the three axes A plate cut from such a crystal at right angles to any axis would present the appearance shown of a rectangular network of wires (Fig 1) When such a plate is magnetized in the direction of the axis *AB* the magnetic force unless it is extremely strong exerts an appreciable magnetizing effect only upon the wires which are parallel to *AB* as it is very difficult to magnetize a thin wire transversely Hence the magnetization affects only one-half of the wires of which the plate is composed If on the other hand the magnetic lines of force run in the direction of the diagonal *CD* both the wires parallel to *AB* and the wires at right angles to *AB* become magnetized In this case only a component of the magnetic field acts upon each group of wires but as each component exceeds 70 per cent of the entire strength of the field the total magnetization produced is greater than in the former case in which the field was parallel to the axis It can be computed that this difference begins to manifest itself when the strength of the field is about 40 gauss The vanishing of the difference in very strong fields is explained by the fact that in such fields even the wires which run transversely are magnetized to saturation.

Prof Weiss has proved the general correctness of this explanation by constructing such an artificial plate of fine iron wires and showing that its magnetic behavior is identical with that of the plate cut from the crystal of magnetite. Of course we are not to regard the crystal as being really composed of iron wires The same results would follow if the molecules were arranged in strings like beads, and these strings were stretched in the directions of the three axes (Fig 2) Here the molecules form the apices of small cubes and the structure is called a cubical spatial arrangement or space grating' (Raumgitter) Hence the magnetic properties of magnetite bring us back to the old space grating theory which has long been used for the explanation of other properties of crystals

In the more exact investigation of magnetite which was undertaken by the writer in connection with these first experiments other very remarkable phenomena were discovered in some plates cut perpendicular to the axes of magnetite crystals In the weakest field of 31 5 gauss the magnetization was stronger along one diagonal and weaker along the other than along the axes As the strength of the field was increased the magnetization along the weaker diagonal increased rapidly attaining the value of the axial magnetization with a field of 63 gauss As the strength of the field was further increased the phenomena approached more and more closely to those of the typical plates first described

How can we explain these remarkable results? Shall we assume that magnetite which has always been regarded as a typical representative of the regular system of crystallization belongs to that system only in appearance? After very thorough investigation I concluded that magnetite does crystallize regularly and that the results above observed are secondary phenomena caused by fissures in the substance of the crystal I picture the crystal crossed by numerous narrow fissures parallel to each face of the octohedron If the fissures in the various directions are equal in width a plate cut perpendicular to the axis would be represented by the left hand drawing of Fig 3 In this case the fissures diminish the magnetization only slightly and to practically the same extent in every direction If on the contrary the fissures in one plane are wider than those in another a plate cut perpendicular to the axis will be represented by the right hand drawing of Fig 3 Here it is evident that the fissures will diminish the magnetization along one diagonal more than that along the other and that the magnetizations in the directions of the two axes will be equal to each other Increase in the strength of the field will diminish all of these differences

Hence we see that the study of the magnetic properties of crystals gives an interesting insight into crystalline structure The results thus obtained have been confirmed in many instances by observations in other fields of crystallography For example the presence of the fissures mentioned above is indicated by the fact that the cleavage planes of magnetite are parallel with the faces of the octohedron A second proof is furnished by the fact that the octohedral crystals have perfectly smooth and glossy faces but the rhombic dodecahedra always show distinct stripes running parallel with the longer diagonal of the rhomb These stripes are the intersections of the internal fissures with the faces of the crystal

Still more interesting results were obtained with pyrrhotin It was discovered at the outset that pyrrhotin which crystallizes in hexagonal prisms is scarcely susceptible of magnetization along its principal axis The magnetization in this direction is a thousand times less than in the plane at right angles to this axis which may be called the magnetic plane The three secondary crystallographic axes, which lie in the magnetic plane are found to be magnetically unlike The phenomena appear entirely irregular In one plate the greatest magnetic permeability is shown by one axis in another plate from the same crystal by another axis etc Here therefore we have again an apparent deviation from symmetry with the crystalline form But while in the case of magnetite the deviation is only apparent in pyrrhotin it is real The real magnetic properties of pyrrhotin are intelligible only upon the assumption that the crystal, apparently a hexagonal prism is really a conglomerate of elementary rhombic prisms placed in three different positions (Fig 4) We are not to suppose that the crystal is made up of three rhombic prisms, but that it is composed of minute rhombic prisms mingled in an irregular manner, so that one type preponderates in one part a second in another, etc. (Fig 5)

An attempt was made to isolate one of these elementary crystals A crystal which showed a marked preponderance of one of the three elements was cut in two, one of the pieces which showed this preponderance to a still greater degree was again divided and this process was repeated until a number of very small fragments [illegible] was composed almost entirely of a single elementary crystal.

When a plate cut parallel to the magnetic plane of such an elementary crystal was examined it was found that magnetic saturation along one diagonal of the rhomb was produced by a field of a few hundred gauss, while in the perpendicular direction saturation was not complete with a field of 11,000 gauss. For the sake of completeness it may be added that in the direction of the principal axis perpendicular to the magnetic plane more than 200 000 gauss would be required to produce magnetic saturation. The limit of saturation of pyrrhotin is 47 units, about one-tenth that of magnetite and one-thirtieth that of soft iron

These peculiarities of the elementary crystals can be explained by the simple assumption that the molecules are arranged according to a rectangular plan, but at unequal intervals along the three axes, so that they form long rectangular parallelepipeds. (Fig. 6.) It is evident that the magnetic strength would be greater in the direction of *aa*, in which the molecules are nearer together than in the direction of *bb*

In the elementary crystal of pyrrhotin saturation in one direction is produced by a very weak magnetic field When we consider that the fragments examined were very small and always contained some admixture of the elementary crystals of the other two types we may be forced to conclude that, except for these obstacles saturation would have been obtained with a still weaker field Hence Prof Weiss makes the bold conjecture that the elementary crystals of pyrrhotin are always, even in the absence of external magnetic force magnetized to saturation in the direction of maximum permeability This assumption is in harmony with Weiss's electronic theory of ferromagnetism, according to which magnetic saturation in one direction always exists in ferromagnetic substances

This condition of magnetic saturation is not observed in larger fragments of pyrrhotin which contain crystals of all three types so mingled that they almost neutralize each other When the large crystal is placed in a magnetic field the magnetization of the elementary crystals cannot be increased as these are already in the condition of saturation but these crystals are turned more or less and the strength of the magnetization in the direction of the field depends upon the amount of this action

Weiss's theory is not a vague speculation but is supported by many exact measurements of the amount of hysteresis the angle between the field and the induced magnetization etc We are tempted to extend to ferromagnetic substances in general the structure which appears to be possessed by pyrrhotin We may regard each of the small crystals of which iron is composed to be always magnetized to saturation As these crystals lie in all directions they neutralize each other unless they are turned by an external magnetic field so that their magnetic axes become approximately parallel

Hence we see that the study of the apparently recondite field of crystal magnetism on the one hand gives an interesting insight into the structure of ferromagnetic crystals (which can be extended by analogy to other crystals) and on the other hand suggests many valuable inferences concerning the nature of ferromagnetism and magnetism in general. —Prometheus

Chemical Misnomers

The word 'oil' in its more comprehensive and everyday use is made to include hydrocarbons, like petroleum and also many substances that have an oily appearance, such as 'oil of vitriol,' which is not oil at all but sulphuric acid Strictly speaking the mineral oils including all petroleum products, are not oil although we speak of "coal oil" and "kerosene oil," and the companies that supply us with those products are called 'oil companies.

The highest authorities do not include in their lists of oils the mineral hydrocarbons like naphtha, paraffin and petroleum but treat only the two well-defined groups—fixed oils and fats, and the essential or volatile oils

'Copperas" is a conspicuous example of chemical misnomer It is not copper, but sulphate of iron. 'Salt of lemon" has nothing whatever to do with the fruit of the lemon-tree, but is potassium binoxalate, or potash treated with oxalic acid.

Carbolic acid" is no acid, but a phenol In structure it is allied to the alcohols, and has only slight acid properties. "Soda-water" shows no trace of soda; "sulphuric ether" contains no sulphur, and "sugar of lead" is entirely innocent of sugar "Cream of tartar" has no cream, nor "milk of lime" any milk. "German silver" is not silver at all, and "black lead" is graphite, not lead, "Mosaic gold" is a sulphide of tin.

These misleading names have come down to us from the vocabulary of an early and [illegible] chemistry. The popular [illegible] the old terms [illegible] the more scientific nomenclature.

Power Production from Solar Radiation*

A Plan for the Exploitation of Natural Sources of Power

By R. A. Fessenden

The problem of the commercial utilization for the production of power of the energy of solar radiation the wind and other intermittent natural sources is a double one The energy of the sources must first be changed so as to be available in form it must next be stored so as to be available in time

As regards the second of these two points one of the expedients which perhaps naturally suggests itself, namely the use of storage batteries is commercially quite out of the question owing to its high cost The method actually employed is storage by gravity Two reservoirs are constructed one at a considerably higher level than the other and the water is first pumped up and then allowed to fall as desired and to actuate a turbine A cubic yard of water falling through one thousand feet is capable of giving out energy equivalent to one horse-power hour If we consider the possible plans for carrying out this project the arrangement which perhaps first occurs to us is that of building a tank at the top of a tower But this is impracticable for either the volume of water required is excessive or else the height of the tower becomes prohibitive The problem assumes more promising form if the upper tank is built on the level of the ground and the lower tank at the bottom of a deep shaft Estimates were obtained from three different firms of mining engineers in Philadelphia which showed that a shaft one thousand feet deep could be dug properly timbered and the necessary chambers hollowed out at the bottom and ferro concreted so as to withstand the water pressure at a cost not to exceed two dollars per cubic yard Assuming two weeks storage and an efficiency of 75 per cent the capital cost per horse-power will be $37 50 Assuming interest at four per cent and depreciation at two per cent the annual cost of water storage facilities exclusive of the pumps and turbines will therefore be approximately $2 25 per horse power

Tenders for the pumps and Pelton turbine wheels for a 3 000 horse-power plant show that the cost of these is approximately $12 50 per horse power Allowing four per cent interest and four per cent depreciation this makes a total annual cost for pumps and turbines of one dollar per horse power The total annual cost of storing one horse-power by the negative gravitational method is therefore $1 00 + $2 25 = $3 25

As regards efficiency water storage has the advantage over the electric accumulator The energy efficiency of a storage battery is generally given as about 65 per cent i e approximately 80 per cent on charge and 80 per cent on discharge

With water storage it is safe to assume an energy efficiency of 89 per cent both at charge and discharge giving a net efficiency of 80 per cent

We have next to consider the method of obtaining the energy from the sources There are two main sources available solar radiation and the wind

To obtain an idea of the amount of power which solar radiation represents under normal working conditions a long-continued series of measurements were made by Prof Very who found that the amount of solar energy received per annum at the earth's surface on an area one hundred meters square in the places indicated is on an average as follows

	Kilowatt hours
Central Europe	4 000,000 to 6 000 000
Northern United States	5 000 000 to 7 500 000
Southwestern United States	10 000 000 to 15 000 000

As regards the amount of power to be derived from the wind tests made during a period of one year on a steel tower 420 feet high at Brant Rock Mass showed an average of 800 horse power at the shaft of a windmill of 300 feet equivalent diameter These figures are about 30 per cent higher than those obtained by Danish experimenters the difference is probably to be attributed to the fact that the Danish experiments were made near the surface of the ground

To utilize solar radiation it is proposed to use a solar tank containing water heated to about 100 deg C* The steam so generated at atmospheric pressure is to drive a low pressure steam turbine which operates the pump Low pressure working is resorted to because with this arrangement the transparent top of the chamber containing the working fluid can be made very thin and has to withstand practically no pressure The transparent roof is designed of double thickness and contains wire netting imbedded in the glass as a protection against hail The working fluid flows in a thin stream across the bottom of the solar tank and the thickness of the stream is varied automatically with the amount of radiation received

The working fluid contains a small amount of potassium dichromate The glass forming the transparent covering contains a small amount of sulphate of iron sufficient to give it a pronounced greenish tinge It has been found that by this means the glass can be made totally reflecting for wave lengths corresponding approximately to those emitted by the heat of water while remaining fairly transparent to the radiation from the sun The thermodynamic efficiency of the system is approximately fifteen per cent and it is anticipated that about ten per cent would be obtainable on the shaft of the steam turbine

From tenders made the costs per horse power have been found approximately as follows

Solar tank	$10
Low pressure steam turbine and condenser	$2[illegible]
Dynamo	$15

Adding to this the cost of the pumps and the water turbine we obtain a total of $62 50 for the first cost per horse-power for the machinery exclusive of the reservoirs Allowing interest at four per cent and depreciation at four per cent and two per cent for labor we obtain a value of $6 25 per annum per horse power as the cost exclusive of the reservoirs Adding in the cost of the reservoirs we find $8 50 as the actual cost per horse power

It will be seen that these figures compare favorably with the present cost of producing power from coal Moreover these estimates are excessive for the reason that it is proposed to operate a windmill plant in conjunction with each solar radiation plant The load will thus be greatly evened and a much better all-day and all year efficiency obtained because the wind is as a rule more effective during cloudy weather and at night time i e at the time when solar radiation is diminished or absent The storage reservoirs employed in connection with this solar plant are of course available without additional cost for the wind power installation

Assuming a solar tank 200 meters square we may expect to receive a total radiation of approximately twenty million kilowatt hours per annum Assuming an efficiency of ten per cent we should get two million kilowatt hours at the steam turbine shaft On the basis of a seven hour day the solar radiation plant would yield an average of 800 horse-power Adding to this the energy derived from the windmill we obtain a total of about 1 500 horse power

The figures given above are for average conditions The location of the first plant is on the whole much more favorable It is situated at a copper mine where the vertical shaft is already available and where worked out lateral chambers are used for the lower reservoir A portion of the pumping machinery also is provided at the mine thus further reducing the cost of installation

The following is a comparative estimate of the costs of producing one horse power for one year by steam gas engine water power at Niagara Falls and the present method The estimates are based on a plant having a capacity of 100 000 horse power operating under average conditions

Method of generating power	Cost per horse power per year
Steam	$15 00
Gas engine	10 00
Water power at Niagara Falls	3 75
From intermittent natural sources	4 [illegible]0
Water power under exceptionally favorable conditions	2 [illegible]0

It will be seen that while this method of producing power is much cheaper than a steam or gas engine it is approximately on a par with water power under fairly favorable conditions such as prevail at Niagara Falls This is because in the present method and with water power the capital first cost is the determining factor The capital first cost per horse-power by the present method using a solar tank is approximately $62 50 and using windmills in conjunction with the solar tank approximately $4[illegible] The capital first cost at Niagara Falls is approximately $40

The new method gains chiefly from the higher fall and from the cheaper and more efficient water motor also from the fact that only one seventh as much water has to be handled and that there are no dams to build or large buildings to erect It loses from the fact that a pump has to be supplied also a steam turbine and solar tank or windmill The method therefore may not be of so much value in places favorably situated for obtaining water power Localities so favored are however comparatively few in number

*Abridged from a paper read before the British Association for the Advancement of Science

*We are not aware that a temperature so much above [illegible] has ever been obtained in any published experimental work Ed

The Argon Process

In a paper presented to the Academie des Sciences M Georges Claude shows that it is easy to obtain argon in the laboratory by using oxygen furnished by the liquefaction of air to begin with In practice such oxygen is above 96 per cent pure and the principal impurity at least with the oxygen which the Claude process procures is argon whose volatility is intermediate between those of oxygen and nitrogen Only a lack of tightness in the oxygen compression apparatus would give a predominance of nitrogen Oxygen at 96 per cent, for instance contains normally more than 3 per cent of argon and hence it is a raw material which is three times as rich as air for the argon process Besides, the oxygen is much more easily absorbed than nitrogen In the method used by the author, he absorbs the oxygen by means of copper and the nitrogen by that of magnesium We can regain the copper in the metallic state and the expense for magnesium is small owing to the low percentage of nitrogen The oxygen is taken from the steel bottle by means of a suitable expansion valve It is sent into a copper tube filled with reduced copper and heated to a low redness The residue traverses a smaller iron tube full of powdered magnesium heated to redness, and then an oxide of copper tube designed to absorb [illegible] due to any initial dampness of the copper or oxygen The absorption of the oxygen by copper takes place very rapidly and would cause the fusion of the oxide if the delivery of gas were too high but we should avoid such fusion in order to keep up the porosity of the mass this allowing of an easy recuperation of the metal by a hydrogen treatment so that in practice we use continually the same tube For instance he uses a copper tube 60 centimeters (23 6 inches) long and 6 centimeters (2 36 inches) diameter heated over the whole length from the start of the operation by the flame of four Bunsen burners of the butterfly type The tube is charged with 2 5 kilogrammes (5 5 pounds) reduced copper mixed with some fine turnings so as to increase the permeability of the mass An iron tube is charged with magnesium, the tube being 40 centimeters (15 7 inches) long and 3 centimeters (1 18 inches) in diameter, heated to redness on a grating The copper oxide is placed in a silica tube 30 by 2 centimeters (11 8 by 0 78 inches) kept at low redness This apparatus allows of treating 3 liters (85 cubic feet) of oxygen per minute and thus we obtain 4 to 6 liters (113 2 to 170 cubic feet) of argon per hour during 2 hours, or 8 to 12 liters (226 to 339 7 cubic feet) before exhausting the copper The best method of following the operation is to take at the start the densities of the gases collected until we obtain the density due to argon. No new observations need be made before the last half hour for the operation is very regular and the absorption quite complete The recuperation of the copper by hydrogen in the same conditions of heating as above can be completed in less than 1½ hours

The Pennsylvania Railway Company announces that it has instituted a new plan of training men to maintain and operate signals It has appointed four signal apprentices who are college graduates The different divisions of the lines east of Pittsburg have started signal schools where experienced men give instruction to the division signal employees The importance of this step is indicated by the fact that whereas in 1902 there were but 7 891 interlocking functions in operation on the lines east of Pittsburg in 1908 this number was 20 725 These functions are operated by 8 792 levers A total of 12 408 signals is in service covering 3 385 miles of road or over 70 per cent of the mileage Signal apprentices will serve a three years course and will then be eligible for the position of assistant signal inspector in the signal engineer's office After attaining this they will be considered for appointment to the following positions Assistant supervisor of signals supervisor of signals inspector, assistant signal engineer, and signal engineer

The "Holy Mountain"

Exploring in the Sinai Peninsula

By Harold J Shepstone

ALTHOUGH the famous Monastery of St Catherine on Mt Sinai is visited every year by a number of Greek and Russian pilgrims the Sinai Peninsula may be said to be little known either to Europeans or to Americans Yet its ancient history renders it one of the most sacred places in the world while its precipitous mountains wonderful gorges strange fertile oases full of Bedouin life and its monastery perched high up the barren heights make the region one of untold interest to the traveler

In view of these facts an account of a somewhat extensive tour recently made in the Peninsula may not be without interest Our party numbered four each hailing from a different country One was a member of the American Colony in Jerusalem who acted as photographer and with what result the accompanying photographs must testify After getting our permits from the Egyptian War Office we took boat from Suez We also had letters of recommendation to the convent Mt Sinai from the Greek Convent of Cairo As we steamed out of the harbor of Suez looking westward toward the mountains of Atakah there could be seen the probable locality where the Israelites crossed the Red Sea.

Our steamer had seen forty nine years of hard service and bore marks of it on every plank, every door lock seemed to be worn out so that there was continual banging day and night When the vessel pitched and the stern was raised out of the water the rudder shook and vibrated as if it could not stand a second wrench Some few hours out we lost the anchor in thirteen fathoms of water This was daringly recovered by an Arab diver He was let down on a leaden weight, attached a hook to the anchor which was then drawn up In all the man was three minutes under water The deck of the vessel was full of devout Mohammedans making their pilgrimage to Mecca. There were 120 of them, and they seemed enough yet on the previous voyage this same vessel carried 506 of these pilgrims, who by force took possession of the first and second-class accommodations. The crew could offer no resistance as the pilgrims were well armed

Our first view of Sinai [illegible]

steamer entered the harbor of Tor The sun was just rising over the highest peak and it was very impressive and beautiful The little harbor is protected by a natural breakwater of two coral reefs with just sufficient space between them to allow a boat to enter Tor is the great quarantine station of pilgrims returning from Mecca There is an excellently arranged series of buildings for the use of the quarantined pilgrims and the fumigating and disinfecting quarters are colossal structures very modern and quite up to date. This international quarantine station is enlivened during the period of the detention of pilgrims by many thousands of "the faithful camping out, if they are too numerous for the rooms

In 1904 there were as many as 17 000 here at one time There must elapse ten days without a death before the pilgrims are allowed to proceed on their journey and there were many deaths among this great multitude so that it appeared as though they never would be able to proceed. The pilgrims then agreed that for the next ten days there should be no more [illegible]

THE SUMMIT OF JEBEL MUSA WHERE MOSES RECEIVED THE TEN COMMANDMENTS

THE HOLY MOUNTAIN

ing and shifting the sand where the tents had stood revealed the ghastly sight of the remains of several pilgrims, who having died, had been buried in the sand under the tents by their comrades The village of Tor will no doubt dwindle into insignificance now since there is a railroad connecting the Damascus and the Haifa railroad with that of Medina and most of the pilgrims will surely prefer that route But one only hopes that the same energetic measures for preventing the spread of cholera plague etc by these returning hordes of devotees will be adopted by the Turkish authorities at the quarantine station on the Mecca railroad otherwise the health of Europe will be greatly imperiled

As soon as we dropped anchor in Tor harbor a sailing boat came out with the superior of the Greek and another at Tor There are only about 5 000 to 6 000 inhabitants as that is all that can be supported on this barren peninsula. The Arabs are divided into tribes each tribe having a Sheik who wields considerable authority The sacred associations of the region draw a number of pilgrims chiefly Russian and Greek to the Convent of Mt Sinai These, of course need camels to carry them and their water and food so in this way a number of the Bedouins gain a livelihood Many own a few palm trees either on the plain or in the Oasis of Firan They take the dates to Suez on camelback and trade them for corn and millet Although the mountains are so barren yet many shrubs and plants that grow being aromatic are much liked by camels goats and sheep and a fair number of goats and of sheep are raised

northeasterly direction aiming for Wadi Hebran The wind was blowing hard and the sand stung our faces considerably After traveling two or three miles we came to the Oasis of El Wadi where we stopped long enough to water the camels and to fill our water skins from the well of good water From here the ground became less sandy until it finally grew hard and gravelly This continued until we reached the foot of the mountains just as the sun was disappearing when we camped for the night

The view from our tent when we woke early in the morning will never be forgotten The peak of Mt Serbal so rugged and imposing was lit by the sun which was rising over Jebel Ka herin The plain was studded with large boulders of granite which had been washed down by the winter torrents and here

convent there to assist us in landing He told us that our camels were ready and we could at once commence our inland journey When we got to shore however we found that a contract had to be drawn up between us and the Bedouin Sheiks and that trivial affair took no less than three hours to complete satisfactorily As the Bedouins take it in turns to escort parties to Mt. Sinai and every one claimed it was his turn it took additional time to finally settle their fighting and shouting.

The Sinai Peninsula, it may be added is bounded on the north by the desert of Tih or the Wilderness of the Wandering on the south by the Gulf of Suez and on the east by the Gulf of Akaba It is governed by the Intelligence Department of the Egyptian War Office. One officer is stationed at Khalat el Nakhl,

We were very cordially entertained at the Greek convent at Tor during the few hours before our start As soon as we arrived we were taken into the comfortable reception room and the usual jelly served A tray is brought in on which was placed a glass of jelly several spoons and a little glass of date brandy and you are supposed to take a spoonful of jelly only Once one of my friends to whom it was passed and being unacquainted with the customs thought that he had to finish the whole glass of jelly But after five or six spoonfuls finding that impossible the host seeing the predicament my friend was in came to the rescue and explained the manner of procedure

It was about noon by the time we had our loads arranged chosen our riding camels and got started We struck across the desert or plain of El Kaa in a

and the c g w a sl ittim tree S after moving from our camp we came to the entrance of the valley of Wadi Hebran and found on the steep cliffs of the rocky ravine several Sinaitic inscriptions These were mostly Nabataean ut ly a people that inhabited the rock hewn city of Petra and worshiped sun moon and stars

The road along this Wadi is quite good and during the spring there is a stream of water here Even as we passed in September there was water flowing for some distance from the fountain head and all along the sides of the little brook grew luxuriant vegetation At noon time we rested under the shade of a group of palm trees watered by a little spring This was the most beautiful part of the Wadi Here were supported several Bedouin families They were just

gathering their crop of dates The men easily climb the trees and cut the dates off in big clusters These are picked off the stems and dried in inclosures fenced in with palm branches

As we ascended during our ride in the afternoon the valley became more sterile with no water and little vegetation The road too was rough and at a height of 3600 feet we came upon our first sight of the only remains of former habitation These were the Nawamis a sort of low stone buildings which the Bedouins attribute to the Israelites The tradition is that for protection against a plague of mosquitoes they were built by them but scientists think they were either graves or huts of the ancients

As we wished to visit Wadi Firan we left the main route to the convent and camped for the night in a desolate valley with no water and no verdure except some juniper bushes During the night we heard the laughing of the hyenas They are quite numerous here and many of the graves of the Bedouins which we passed had been dug into by these repulsive animals which prey on corpses and carrion In these mountains wild goats are found and occasionally leopards Before sunrise next morning we were off to the Oasis of Firan determined to return to our camp that night We were much struck by the strange suffering from fever, caused probably by the stagnant water in some of the gardens, and a diet consisting almost entirely of dates By noon time we had traversed almost the entire oasis, and came to the ruins of an old convent This was one of the great centers of the Anchorites in the early centuries, and the sides of the valley are full of their tombs They came to this spot as it is at the foot of Mt Serbal which the earliest traditions affirm to be the Sinai of the Bible Later as the monks of Jebel Musa, at the Monastery of St Catherine became powerful, they claimed that around their locality transpired all the acts connected with the giving of the law Eusebius the earliest Christian historian gives the Oasis of Firan as the battlefield between the Israelites and the Amalekites

On our return to camp we simply retraced our steps, returning by the same route we had come and next morning set out for the Monastery of St Catherine As we were traveling along, suddenly one of the Bedouins began examining the ground and following some track He then assured us that a camel of his had passed along there the day before They can tell their own animals by their foot prints, and as they allow them to roam at will over the mountains for months at a time they get very expert in tracking them when they need them They always keep within [illegible] protects it, and [illegible] occurred at [illegible]

One of the monks was appointed our guide up Jebel Musa (mountain of Moses), which we undertook on the early morning of the second day after our arrival. We ascended by the pilgrims' steps, a steep path built by the monks, each step being a slab of granite. A little chapel on the way up marks the spot where the Virgin appeared to the monks as they were deserting the monastery on account of a plague of vermin and promised them deliverance if they would return. They did so and found that the tormenters had disappeared But tourists agree that they have since returned Continuing our upward way we next come to an archway through which the path leads Long ago a hermit named St. Stephenous zealously guarded the gate, and would allow no one to ascend the Holy Mountain unless he could prove his worthiness and that his record was good If this was proved he would administer the sacrament and allow the pilgrim to ascend One day he was found at his post but lifeless

The path after twisting in and out among huge boulders of granite, suddenly opens on a small plateau with a gigantic cypress tree and a round mound or hill in the center The monk told us that here Moses gathered the elders of Israel together Here also is a

seams of black diorite in the gray and red granite slopes These seams run invariably from north to south and the dividing line between the different colors is as marked as if it had been cut with a knife As we neared Wadi Firan we could see where the valley narrowed to only a few yards in width This was at El Huwah the Arabic for little door Undoubtedly this pass was utilized by the Children of Israel in their journey to Sinai as there is no other route practicable for a large body of people

Soon after this as we turned a bend in the valley a most exquisite picture met our eyes It was the beginning of the Oasis of Firan the veritable Pearl of Sinai Out of the apparently parched desert sprang a beautiful stream of water making an Eden of the next seven miles of the Wadi No one can appreciate such a change such a jump from sterility into fertility unless they have actually traveled the weary desert and come to such a haven Our ride through the palm gardens was very enjoyable as they were full of Bedouin life At no other season of the year could we have witnessed the date harvest which was just being gathered After the dates are gathered almost all the Arabs leave the gardens and seek the hills and plateaux where pasture is obtainable for their animals. We noticed that many people in the oasis were a few hours journey from a spring The road was very rough and tedious at Nabk el Haweh, but we were well repaid when we got to the summit of the defile The view was grand and commanding. Jebel Musa Jebel Katherine and many other peaks loomed into view From here our goal was in sight A ride of a few hours more brought us to the hospitable Monastery of St Catherine We pitched our tent in the convent grounds and at once went to pay our respects to the monks and to present our letter of introduction They had already got word of our coming, so were on the lookout for us.

The monastery or convent as it is generally called although only monks reside here is built in a narrow valley, at the foot of Jebel Musa. It has almost the appearance of a fortress having a massive wall surrounding it And such it was for we learn that Justinian built a fort on this site in the fourth century expressly for the protection of the monks. He also strengthened them by a present of 100 Roman and 100 Egyptian slaves with their wives and children. The descendants of these very slaves, the Jebeliyeh, still live at the convent and serve the monks, although they have adopted Mohammedanism. There are now about twenty five monks living here, Greeks from Cyprus or Crete. As the church is Greek Orthodox, Russia [illegible] chapel said to mark the cave where the prophet Elijah rested when fleeing from Jezebel, and where he heard the still small voice From this point to the top the ascent is very steep but thanks to the monks, it is not difficult, as they keep the steps in repair The whole summit of the mountain is a huge mass of solid granite The upper point is over 700 feet high and here is pointed out the rock where Moses saw the glory of God pass by and where he received the Ten Commandments Some one described the view from here as looking upon an enlarged section of the moon. It is well put for no greater desolation or bleakness could be found anywhere Jebel Katherine close by, is very imposing It is the highest peak of the range Toward the east are seen chain after chain of somber looking mountains and beyond the Gulf of Akaba.

After descending to the monastery we spent the rest of the day in visiting the locality where Aaron made the "Golden Calf" and then on the Plain of Er Raha. This is a broad fine plain at the foot of Jebel Safsaf and Jebel Musa, where Israel must have camped while Moses ascended Sinai. The following morning we devoted to the monastery The present entrance is through a small, heavy iron door in the western [illegible] [illegible]

used in case of a siege. Until recent years visitors were admitted to the monastery by means of a rope, which was attached to a person, who was then drawn up over the wall.

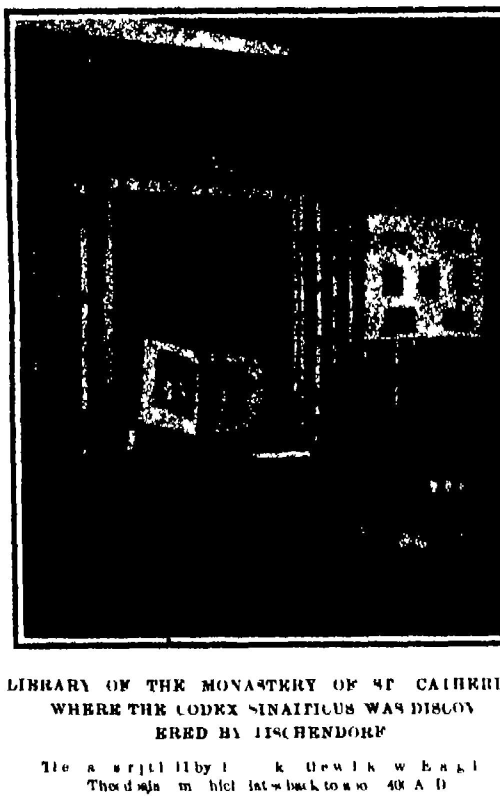
On entering we were much surprised at seeing the minaret of a mosque side by side with the bell tower of a Christian church. We learned that the erection of the mosque was a diplomatic move on the part of the monks to save themselves from massacre by the Mohammedans, since through their care of the mosque they thus obtained the favor of the Islams The church is an early Christian structure built in memory of the Transfiguration of Christ The mosaics which adorn the apse are very old and very valuable The monks took us to one side brought a table and with an air of great mystery opened a small marble sarcophagus out of which they took the skull and one hand of St Catherine the martyr of Alexandria These remains were bedecked with most costly jewels Each of us was presented with a souvenir ring taken from the coffin

We next visited the Chapel of the Burning Bush where we had to take off our shoes for it was holy ground The library was of most interest to us as this is where Prof Tischendorf discovered in 1844 the Codex Sinaiticus a Greek manuscript of the Old and the New Testament It dates from 400 A D He was a German scholar and devoted his whole life to the discovery and the study of ancient biblical manuscripts On this errand he visited all the libraries of the East but quite unexpectedly found this the "pearl of all his researches in the Sinai convent He saw some leaves of parchment in the waste paper basket and was told that two similar lots had been burned Among them were parts of the Greek Septuagint the oldest looking manuscript he had ever seen He was allowed to take what he wished of them and got forty sheets but he displayed so much joy with his gift that the monks suspected their value and would give him no more On his return to Europe he tried by every means to procure the remaining sheets but without success Fifteen years later he returned to Sinai armed with letters from the Czar On knocking at the door of the convent one of the monks put out his head over the ramparts and after receiving his letter the monks lowered the rope and hoisted him up Still he accomplished nothing and was preparing to leave when the steward of the convent invited him into his cell and showed him a bundle of old manuscripts which he found was just what he was searching for This time he concealed his joy and carelessly asked if he could take them to his room while he found out their real value They were given to the Czar and are now in the library of St Petersburg

Our return to Tor was by a different route from the one we came by We went south and followed Wadi Isla This is the most picturesque gorge in Sinai especially for the grandeur of the precipitous rocks or cliffs that inclose it They rise on either side in some instances two to three thousand feet The bed of the torrent is narrow not exceeding five yards in some places and through this rushes a mighty volume of water after a rain storm sweeping all before it We camped for the last night of our desert journey at the mouth of this gorge It was most oppressive and hot At midnight the thermometer registered 100 deg F!

Alcohol

NUMEROUS alcohols are known to the chemist but that which he describes as ethyl alcohol is the one which is meant when we speak simply of alcohol Primarily it is obtained by distillation from a great variety of materials—wines sugars grain and various other substances—each of which yields a spirit containing various ethers, essential oils and other compounds which give it a characteristic odor and flavor When intended for drinking purposes in the form of whisky etc the retention of some of these various ingredients is necessary but by a special process of distillation it can be obtained free from them in which case it is known as "patent or 'silent spirit Water is always present in this and the strength of the silent spirit may vary greatly One particular variety of still is reputed to produce silent spirit containing only 2 per cent of water which is practically equivalent to what we call absolute alcohol but usually there is much more water than this and the spirit has to be "rectified by redistilling In the more ordinary process of production the result of repeated distillation or rectification is a product containing about 90 per cent by volume of pure alcohol and 10 per cent of water, which is known as rectified spirits or spirits of wine Continuing the same process will not reduce the quantity of water any further and treatment with lime is necessary before a stronger spirit can be produced. By such treatment it is, however, possible to get rid of nearly all the water, and when not more than 1 per cent remains the fluid is called absolute alcohol. The actual strength of this is usually about 99.5 per cent. This is, of course, the purest and strongest alcohol obtainable but it is expensive, and stronger than is always required If it is to be used mixed with water, we may just as well purchase a weaker and slightly cheaper variety and the next definite strength is the so-called rectified spirit" which contains 84 per cent by weight or nearly 90 per cent by volume of pure absolute alcohol This



LIBRARY OF THE MONASTERY OF ST CATHERINE WHERE THE CODEX SINAITICUS WAS DISCOVERED BY TISCHENDORF

The [illegible] by [illegible] The [illegible] back to [illegible] 400 A D

rectified spirit is also known as spirits of wine but the latter term being also used somewhat vaguely to cover alcohol in general it is usually best to ask definitely for rectified spirits

The next definite strength of alcohol is known as proof spirit or as spiritus tenuior by the druggist This is a standard strength adopted by the revenue authorities and it contains 49 per cent by weight or about 57 per cent by volume of pure alcohol Other strengths of alcohol are frequently described in terms of proof spirit so that it is well to understand what it means Rectified spirit is often described as 56 over proof which means that the addition of 56 parts by measure of water to 100 parts of rectified spirit will give proof spirit It also means that we must take 156 parts of proof spirit to get as much alcohol as is contained in 100 parts of rectified spirit Weaker spirits are styled under proof and 20 under proof means that 100 parts of the spirit contain only 80 parts of proof spirit It is necessary to avoid confusing proof spirit with absolute alcohol which is nearly double its strength

A good deal of confusion has arisen over the matter of methylated spirit Originally methylated spirit consisted of a mixture of 90 per cent by weight of rectified spirit with 10 per cent of wood alcohol or wood naphtha This compound was sold duty free and could be used for most of the purposes for which pure alcohol was wanted excepting of course that it could not be used in medicines and it was assumed that no one would care to drink it as a beverage This assumption proved however to be a mistake it was drunk in large quantities and so some years back petroleum was substituted for the wood spirit the new compound being very unfortunately still called methylated spirit This is allowed to be sold as freely as the old spirit but restrictions have been placed upon the sale of the original real methylated spirit The newer compound miscalled methylated spirit but more properly described as denatured spirit is useless for most of the purposes for which the older variety was employed It is indeed of little use for anything except burning and the manufacture of varnishes It cannot be used as a cheap substitute for pure spirit in chemical and photographic work and therefore if the cost of pure spirit is a consideration the old methylated spirit which is now known as industrial spirit must be procured

Unfortunately there is yet another variety of so called methylated spirit which consists of the ordinary denatured spirit with one ounce of shellac dissolved in each gallon This is technically called methylated finish but oilshops frequently supply it when methylated spirit is asked for Indeed in some cases it is the only kind kept in stock

Alcohol is used for a variety of purposes in photography for drying negatives mixing carbon sensitizing baths making varnishes and sometimes for dissolving developing agents For all these purposes industrial alcohol can be used safely though we prefer pure spirit for developers In making up solutions with alcohol there are one or two points that should be noticed A mixture of alcohol and water is of less bulk than the sum of the volumes of the two ingredients the shrinkage being greatest when 52.3 measures of alcohol are added to 47.7 of water The total measure of the mixture is not 100 but only 96.36 measures so that the diminution of volume is 3.64 per cent The most important point to observe is that this shrinkage of volume is accompanied by a marked rise of temperature so that if we add a developing agent dissolved in alcohol to water at normal temperature the mixture will for some few minutes be well above the normal temperature and the resulting developer may be too warm It should therefore always be cooled down before use—British Journal of Photography

French Butterfly Farms

THERE are in France butterfly farms the object of the farmers being to rear rare genera of the Bombycidæ the silkworm family By crossing some new varieties have been obtained and these are much sought after by museums of natural history

Endeavors are also being made in France to acclimate species of silkworms indigenous to other countries The farms contain oaks ailanthus trees pines plum trees castor oil plants and other plants the leaves of which serve as food for the caterpillars Cocoons are hatched on branches protected by gauze and for the sake of uniform temperature the insects are often kept in a room until after the first molting when they are placed on bushes in the open air and protected from birds by coverings of muslin or tulle

PRIMITIVE ELEVATOR IN THE MONASTERY OF ST CATHERINE NOW IN ACTUAL USE

THE HOLY MOUNTAIN

The Knight Valveless Motor

A Highly Efficient Hydrocarbon Engine

The earliest explosion motors those of Lenoir and Otto were constructed on the model of the steam engine from which they borrowed the slide valve Separate valves of the ordinary type were subsequently adopted and for many years such valves were employed in all explosion motors but a tendency to revert to the original solution of the problem has recently become manifest In several motors of recent invention the valves are replaced by sliding devices which however are not operated by the piston and bear no resemblance to the slide valve of a steam engine

Separate valves have been tried and condemned They are accused of causing many breakdowns due to broken valve rods and adhesion of the valve to its seat They also throttle the entering stream of gas and make too much noise It is true that some motors provided with valves are almost silent and that most of the objectionable features of the valve are not inherent but are due to faulty construction At very high speeds however the valves fail to follow the contour of their operating cams accurately and run wild causing a great loss of power as shown by the indicator diagram

Hence valveless motors are coming into vogue The new Knight Hewit, Bingham Mercedes and Rénaud motors are of this type The Knight valveless motor which appears to be nearly perfect in construction and operation is now made and used by the celebrated automobile firms Minerva in Belgium Pankard-Levassor in France Mercedes in Germany and Daimler in England

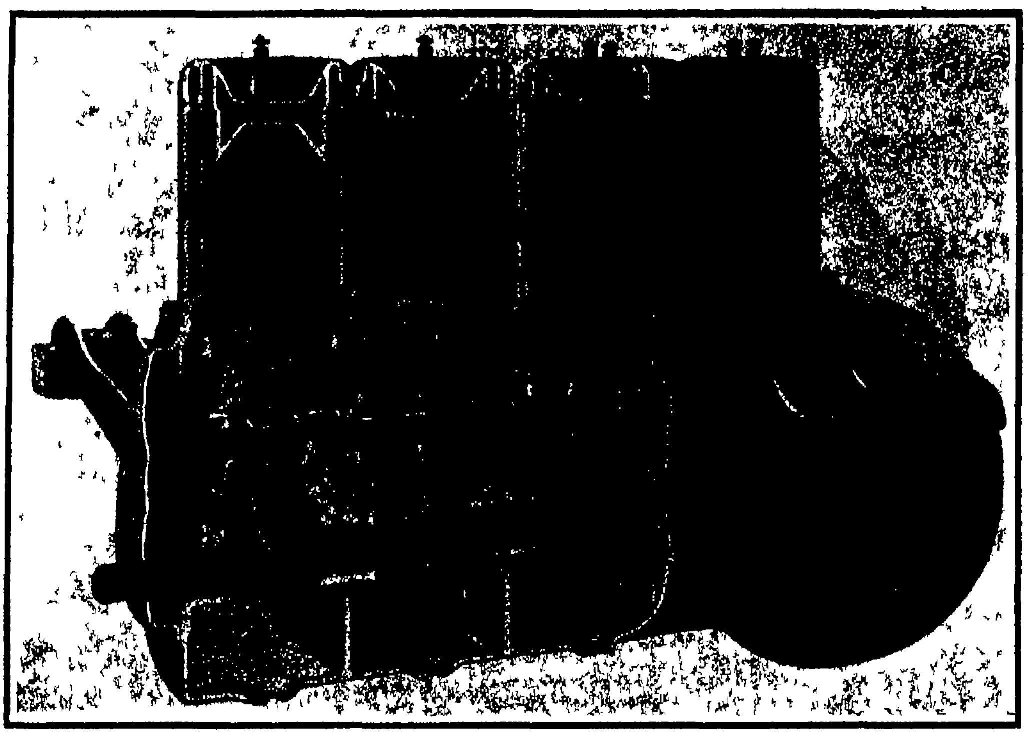

Fig 1 —THE KNIGHT VALVELESS MOTOR

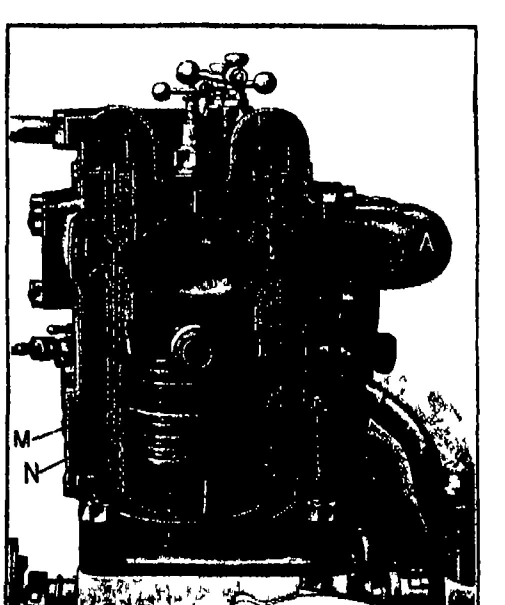

Fig 2 —VERTICAL SECTION OF CYLINDER OF KNIGHT MOTOR

The Minerva Knight valveless motor has four cylinders connected in pairs The top of each cylinder has two lateral orifices which communicate respectively with the supply pipe *A* and the exhaust pipe *E* (Fig 2) The cylinder is surrounded with a water jacket and is lined by two thin hollow cylinders or sleeves *M* *N* which have large lateral openings and which move in such a manner that they control the aspiration and exhaust of gas by bringing these openings opposite the smaller orifices of the large cylinder at the proper times These sleeves are moved up and down by the rods *E* and *F* connected with eccentrics on the shaft *A* (Fig 3) which makes one revolution in each two revolutions of the main shaft *G* In a motor of 35 horse-power the travel of the sleeves is one inch while that of the piston is more than five inches Hence the velocity of the sleeves is less than one-tenth that of the piston The openings in the sleeves are so wide that the gases enter and leave the cylinder much more freely than they could do through valves

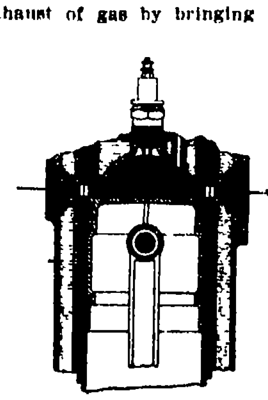

Fig 4 —THE ARROWS SHOW THE SHORT AND STRAIGHT COURSE OF THE GASES IN A VALVELESS MOTOR

The motions of the sleeves and the positions and dimensions of their openings are so adjusted that each port is closed by one or both sleeves during three fourths of the cycle and is kept open during the remaining fourth of the cycle by the simultaneous apposition of the openings in both sleeves upon the orifice in that side of the cylinder During the first down stroke of the piston (aspiration) the inlet port is open and the exhaust port closed during the first up stroke (compression) and the second down stroke (explosion) both ports are closed during the second up stroke (exhaust) the exhaust port is open and the inlet port closed At the end of the cycle, however the exhaust port remains open for a very short time after the inlet port has opened so that the products of combustion are completely expelled by the entering gas

This motor is very silent, especially at high speeds, and is so flexible in operation that the speed of an automobile can be varied within very wide limits by simply controlling the admission, so that the differential need not be used, except for starting and backing Another great advantage is presented by the constancy of compression which is difficult to obtain with ordinary motors because of leakage at the valves which also causes the carbureter to work badly and produces a loss of power The absolute constancy of compression in the Knight motor is the cause of its perfectly uniform speed for the intervals between

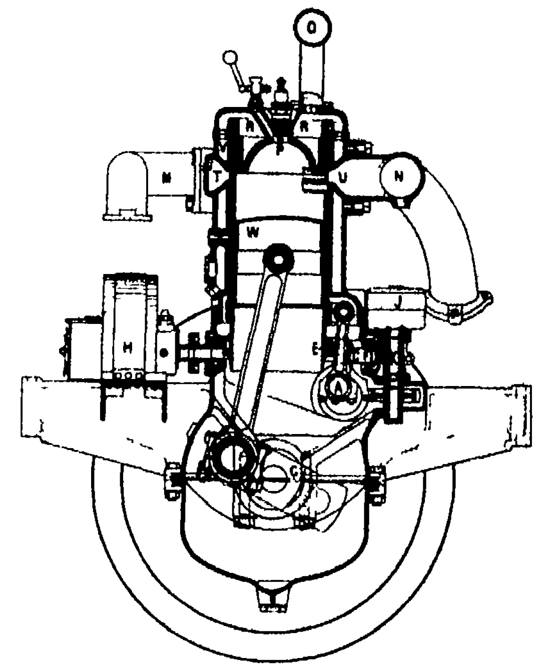

Fig 3 —DIAGRAM OF CYLINDER OF KNIGHT MOTOR

successive explosions cannot be vigorously equal unless the compression is always exactly the same in all of the cylinders In order to satisfy this condition there must be no leakage and the cylinders must be exactly equal in volume It is impossible to obtain this perfect equality in castings but the cylinders of the Knight motor are worked to the required dimensions and polished so that they present no projections containing particles of carbon which might become incandescent and cause premature explosions

The moving sleeves are lubricated by oil which is drawn by capillary action between them and between the outer sleeve and the cylinder and which fills horizontal grooves on the outside of each sleeve (Fig 2) In these conditions the width of the interval between the surfaces is within reasonable limits, of comparatively little importance All escape of gas during the compression is prevented by a ring *S* (Fig 2) which is pressed upon the inner sleeve by a spring and by a thin layer of oil between the ring and the sleeve

The vital parts of the Knight motor are the moving sleeves and the rods which connect them with the eccentrics At 1 200 revolutions per minute, the normal speed of the 35 horse-power motor the mean velocity of the sleeves is only 100 feet per minute

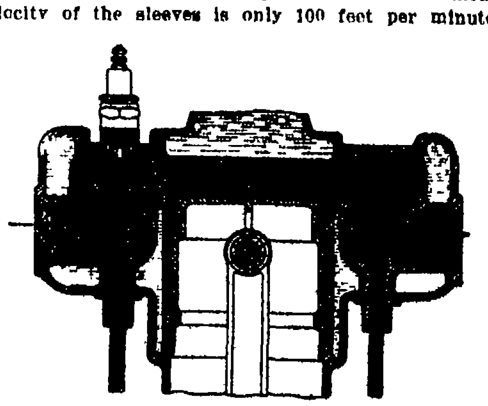

Fig 5 —THE ARROWS SHOW THE LONG AND CROOKED COURSE OF THE GASES IN A MOTOR WITH VALVES

The maximum stress exerted upon the sleeve by the connecting rod is 62 pounds for the inner sleeve and 33 pounds for the outer sleeve. Hence, there is practically no danger of fracture. The wear of the sleeves and the power consumed in operating them are also negligible. As they are driven by eccentrics, and not by cams, they cannot go wild at the highest speeds. They open and close the ports exactly at the proper instants and their openings are so large that the power of the motor increases with its speed.

In a comparative test of two similar motors and

with valves and the other without the valveless motor developed 30 and the valved motor only 25 horse power at 3,000 revolutions per minute. In another comparative test of two larger motors the valveless motor developed nearly 45 and the valved motor barely 35 horse-power at 1,800 revolutions. In each case the introduction of the sleeves made the effective diameter of the valveless cylinders smaller than that of their competitors, the difference amounting to ⅛ inch in the smaller and 1/6 inch in the larger motors. The inventor claims that the power consumed by the motor itself has been measured by experiments in which the motor was driven without gas by an electric motor and has been found to be only 13 per cent of the power developed by the motor when operated normally at the same speed so the efficiency of the Knight valveless motor is 87 per cent.

The form of the explosion chamber deserves special notice. Both the top of the cylinder and the top of the piston have a spherical curvature and the concavities of the two face each other. By this construction the surface is reduced to a minimum with respect to the volume and the exploding gases retain their heat and pressure longer than they would in a chamber having sharp angles between its bounding surfaces. The result is a smoothness and flexibility of operation comparable to those of a steam engine.

The Knight valveless motor has been subjected to many tests which have yielded some surprising results. For example a motor which produced 55 horse power at 1 140 revolutions per minute at the beginning of the experiment developed 56 horse power at 1 180 revolutions after running one hour. A motor of 38 nominal horse-power with cylinders measuring about five inches each way developed 55.3 horse-power continuously during a run of 5 days and 14 hours at 1 200 revolutions per minute and consumed 0.85 pint of gasoline per horse-power hour. The motor was then placed on a car weighing about 2 tons which made a tour of 2 1?4 miles at an average speed of 42.4 miles per hour. The motor was returned to the shop where it developed an average power of 57.25 horse-power during a run of hours at 1 200 revolutions and consumed 0.?? pint of gasoline per horse power hour. Hence it had gained 2 horse-power by use.

The valveless motor especially as it is represented by the type above described marks great improvement made at a time when the explosion motor was believed to have attained its maximum efficiency. It can be surpassed only by the turbine.

The Geological Society of America

Report of the Annual Meeting at Pittsburgh, Penn

By E. O. Hovey

The twenty third annual meeting of the Geological Society of America was held in the Carnegie Museum Pittsburgh on December 27th-29th 1910 under the presidency of Arnold Hague LL.D. of the United States Geological Survey. About one hundred members were in attendance and forty five papers were on the programme thirty one of which were read in full or presented in abstract with the aid usually of lantern slide illustrations and numerous diagrams and maps. One of the principal papers of the meeting was the address of the president upon The Origin of the Thermal Waters in the Yellowstone Park in which Dr. Hague summed up the results of many years of study in the park carried on mostly by him self and by parties working under his direction. He concludes that the waters of the geysers and springs are meteoric in origin and that their elevated temperature is due to aqueous vapors rising from the deeply buried but still hot igneous rock of the region.

Of the papers presented by other members of the Society by far the most important was that by Dr. E. O. Ulrich of the United States Geological Survey entitled Revision of the Paleozoic Systems of North America. This revision takes into consideration all the work done upon these widespread fundamental formations for the past three-quarters of a century and will form an octavo volume of about three hundred pages when published. It will doubtless arouse more discussion than any similar attempt at exact classification that has been undertaken.

Mr. N. H. Darton of the United States Geological Survey gave a brief summary of the results of studying the List of Underground Temperatures in the United States that he and several associates have been gathering together during the past fifteen years. A self registering thermometer of special type has been used in making observations in about one thousand deep borings. The rate of increase of temperature has been found to be quite variable but in places there is a marked relation to the geologic features of the region.

An Unusual Distortion of the Lower Kittanning Coal was the title of an interesting communication presented by Mr. Richard R. Hice of the State Geological Survey of Pennsylvania. Of the whole Allegheny series in western Pennsylvania no horizon is more regular and continuous than the Lower Kittanning coal indeed with its accompanying clay it is one of the best keys of the series. While there are many changes and local variations in the sandstones and shales caused in many cases by distinct erosion intervals this coal while not always workable is uniformly found over a large area. It is not marked by distinct foldings or distortions but by parallelism with both the under and overlying strata. At the site of Dam No. 5 on the Ohio River on the eastern edge of the Beaver Quadrangle between the towns of Rochester and Freedom a recent railroad cut exposes in a distance of some 600 feet a series of foldings involving the strata between the base of the Lower Kittanning clay and the horizon of the Middle (Upper) Kittanning coal (about 35 feet) in no way involving the underlying strata or those above the horizon of the Middle Kittanning coal.

The next paper was by Mr. W. T. Lee of the United States Geological Survey upon Further Evidence of an Unconformity in the So-called Laramie of the Raton Coal Field, New Mexico. This important series of coal-bearing rocks is now shown to be divided into two parts, each of which carries coal and the evidence is now pretty conclusive that there was a time break between the two formations. The lower is variable in thickness, and the observations indicate that the ancient surface represented by the unconformity was an undulating plain. Furthermore the character of the conglomerate base of the upper basin shows that this plain was one of erosion.

Professor William H. Hobbs of the University of Michigan followed with a suggestive paper on Repeating Patterns in the Relief and in the Structure of the Land. This paper was a discussion of patterns of relief which in many districts repeat themselves like a diaper design in architectural ornamentation. Such patterns have their origin in a fracture system intersecting the outer shell of the lithosphere and are best displayed in high latitudes because there the vegetable cover is scanty and frost action is the dominant weathering process. Where a country has further been partially submerged through depression the expression of such patterns is strikingly brought out in landscape and map alike. Studies made in Norway during the past season have shown that the origin of such patterns in that district is in part explained by the spreading of joint walls at more or less regular intervals within each series and resulting heavy frostwork on these planes. A line of drainage once established stream erosion and in some cases mountain glaciation have shaped the valley which is excavated. Patterns of relatively small size not only repeat but further group themselves into diaper like patterns of higher and higher orders. A compilation of data from widely separated districts in both North America and Europe reveals the existence of a primary pattern common to all areas which is however locally obscured by the superimposition of additional disorderly fractures. Much light is thrown from these studies upon the nature of geological faults which is also confirmed by later studies in seismology.

The upper surface of the great Triassic trap sheet in Montgomery County Pennsylvania sometimes shows a network of lines which closely resemble the sun cracks produced in a dry mud flat. These were described by Mr. Edgar T. Wherry of Lehigh University who stated that the lines were shown by a thin section to consist of coarsely crystallized augit and feldspar traversing a fine-grained ground mass and he accounts for them by regarding them as shrink age cracks developed by the sudden cooling of the molten trap against the contiguous shale the cracks being then filled up by molten material from the interior of the igneous mass.

A note of the recent International Geological Congress which was held in Sweden was given in a paper by Professor James F. Kemp of Columbia University who described certain of the pre-Cambrian rocks of Sweden and compared them with the corresponding rocks in North America. Much of Sweden is occupied by granites gneisses and schists which bear interesting resemblances to similar rocks in Canada, New England, the Adirondacks and other American regions. These Swedish beds are economically important for their content of iron ores and for their value in some places as sources of building and ornamental stones.

This paper was followed by one on The pre-Cambrian of Southeastern Ontario by Willet G. Miller and Cyril W. Knight of the Canadian Geological Survey. This region is classic ground in American geology and its rocks form an important part of the geological backbone of the continent but they are extremely complicated in their relations one to another and they still furnish field for active investigation.

A sketch of the local geology of the city of Pittsburgh was given by Dr. Percy E. Raymond formerly of the Carnegie Museum, but now of the Canadian Geological Survey. Dr. Raymond said in part: The city is situated along deep trenches, cut by the present rivers and in abandoned valleys of preglacial streams. Both were cut in a nearly level plateau, whose surface is from 500 to 600 feet above the present water level. Terraces and river gravels are well exhibited at many places along the abandoned valleys. The strata underlying the city are of middle and late Pennsylvania (coal measures) age, almost the whole of the Conemaugh and Monongahela series being well exposed. The nearly continuous exposures along the rivers afford an excellent opportunity for tracing the various beds and many interesting changes in sedimentation including erosional unconformities may be seen.

Professor Gilbert van Ingen of Princeton University in a paper upon The Shawangunk Grit and its Facial Relationships brought out the shallow water origin and shore characteristics of this small but important formation stretching from Shawangunk Mountains southwestward into Pennsylvania.

Then Dr. Percy E. Raymond described briefly the Chazy Formation in the Ottawa Valley making some new subdivisions and correlations with the New York beds and showing the influence of ancient geological features as barriers to the movement of animal life.

Professor D. W. Ohern of the University of Oklahoma gave a paper upon The Stratigraphy of the Lower Pennsylvania (coal measures) of Northeastern Oklahoma in which he gave a brief summary of the subdivisions of some two thousand feet of rock strata covering an area of some 3 700 square miles. The beds consist of limestones rich in fossils sandstones and shales poor in fossils and some beds of coal.

A paper by Professor William J. Sinclair of Princeton N. J. and Mr. Walter Granger of the American Museum of Natural History described in some detail the Eocene and Oligocene of the Wind River and Big Horn Basins in which the authors stated in brief that a comfortable superposition of Wind River beds on Wasatch and unconformable lower Oligocene on Uinta Bridger Lower Eocene have recently been found in the Big Horn and Wind River Basins respectively in northwestern Wyoming. These structural depressions partly inclosed by the Big Horn Bridger Owl Creek and Wind River Mountains were receiving sediments during the Wind River and Lower Oligocene but since then have been subjected to deep dissection by streams and wind erosion exposing sections of the tertiary filling. Nonvolcanic sediments predominate in these tertiary beds derived in large part from the rocks of the surrounding mountains shown by the abundant granite gneiss and sandstone pebbles in the channel sandstones interstratified with the alternately banded red and blue or yellow clays of the Wasatch and Wind River and by the presence of arkoses in the Uinta. Explosive volcanic eruptions are indicated by a few narrow tuff bands in the Eocene (Wind River) but especially by a great flow of andesitic agglomerate in the Lower Oligocene. Fine wind blown silts highly calcareous marls and siliceous spring deposits (chalcedony and opal) characterize the Oligocene above the horizon of the volcanic mud flow. Suggestions were offered in explanation of the alternation of color bands in the Eocene clays based on lithologic and paleontological data. Early Tertiary orogenic movements involving renewed uplift of the Big Horn arch are demonstrated by a great marginal anticline found in the Wasatch and by the numerous sandstone dykes apparently of seismic origin contemporaneous with the accumulation of the Wasatch clays.

A Quantitative Classification of Meteorites by Dr. Oliver C. Farrington of the Field Museum of Natural History is an attempt to arrange meteorites in accordance with the quantitative system of petrology as proposed by Messrs. Iddings, Cross, Pirsson and Washington. One hundred and twenty five meteorites have been assembled all of which fall within two

classes of basic lavas as proposed by these authors but the majority of the falls are outside of the groups in which terrestrial rocks actually occur

Some important papers on economic geology were read The first of these was by Professor J A Bownocker of the State University of Ohio upon The Clinton Sand as a Source of Oil in Ohio The author related the history of the exploitation of gas and oil in different parts of Ohio with particular reference to the distribution of the Clinton sand and its position somewhat east of the center of the State where productive The sand was originally correlated with the Clinton formation of New York but it is now considered to be older It outcrops in the extreme south western corner of the State where it is barren, but it lies so low in the eastern part of the State that it has not been reached by the deepest borings The wells from this sand have furnished first gas and then oil the latter sometimes being of remarkable clearness and purity Explorations are now in progress looking toward the extension of the oil producing territory toward the north central part of the State

This paper was followed by a valuable contribution entitled Notes on the Geological Relations of Oil Pools Situated in Regions of Monoclinal Structure by Dr Frederick G Clapp of Pittsburgh Pa The author said in part Particular reference is made to the oil pools of southeastern Ohio which may nearly all be classified as situated on monoclinal structures Geologists and oil men have generally assumed that geological structure was of little assistance in predicting the positions of pools of this class The main object of this paper is to show that geology is of great value in this as in other classes of oil fields and that good predictions may be made The detailed structures of several well known oil pools are given as examples It has been discovered that in the great majority of cases the oil has accumulated at positions where the change in rate of dip is commonly proportional to the abnormality of the generally uniform dip The positions of accumulation are also influenced by structural ravines crossing the sand Although the structure of the sand may be quite different from that of the surface formations it can nevertheless be calculated to a considerable degree of accuracy from the surface by taking into account the change in intervals which is comparatively uniform for a given locality

Metal mining was not entirely overlooked on the programme and an interesting paper by Professor Frank R Van Horn of the Case School of Applied Sciences Cleveland Ohio dealt with The Occurence of Silver Copper and Lead Ores at the Vota Rica Mine Sierra Mojada Coahuila Mexico The author said in abstract These ores occur on the contact or a short distance below the contact of an acid breccia with an underlying limestone of Cretaceous age There are some indications of a fault plane between the two rocks such as clay selvages and slickensides There are two types of ore a silver lead and a silver copper series In the former group the minerals are all oxidized and consist chiefly of argentiferous cerussite along with native sulphur and some gypsum The bulk of the ores from this mine however seems to belong to the silver copper group and contains sulphides as well as oxidized minerals Minerals noticed here were chalcopyrite chalcocite covellite along with native copper malachite azurite cuprite and gypsum Another zone consisted of a siliceous limestone containing up to 10 per cent of barite which was impregnated with cerargyrite and native silver Here the copper content was smaller, and rarely exceeded 2 per cent Some three years ago a fault was discovered in the northern part of this silver-lime ore body Along this fault plane, silver and copper minerals of great richness were found mixed with more or less barite Some of the minerals noticed were native silver argentite, proustite, and pearceite, which has been found in but two or three localities in the world At this point a mixture of erythrite and barite was also noticed which seems to be the first observation of cobalt minerals in the district.

Turning to the glacial and physiographic section of geology there were several papers of considerable local interest, and others of wider bearing Among the latter may be mentioned one by Dr William C Alden of the United States Geological Survey upon Radiation of Glacial Flow as a Factor in Drumlin Formation There is a very notable development of drumlins in central eastern Wisconsin These are grouped in three more or less distinct sets corresponding to each of which there is a set of marginal moraines which are believed to mark the limits of the glacial lobe during the stages when the drumlins were being formed The outer moraine of each set marks the limit of the re-advance of the ice after an interval of recession The drumlin belts and moraines show that the ice was radiating widely to the curved margin of the lobe where it became thin in consequence of the radial spreading and of the loss by melting and ablation Computations show that the spreading of the ice under its own weight alone would not account for its remarkable expansion Hence only the forward crowding of the more rapidly moving ice at the rear (north) could have supplied the requisite volume Though the stream expanded greatly so that friction was much increased the remarkable development of drumlins indicates that the basal ice did not clog Such basal movement was probably due to the ice being shoved bodily forward by the vigorously advancing ice in the rear this forward shove being superimposed on such internal flowage as was taking place It is believed that the application of such propulsive force in the region of the center of radiation of such as mass which was tending to lag in every part owing to great friction would tend to cause the longitudinal lines of flowage to spread and so develop stress along transverse lines These stresses though perhaps not causing the actual opening of longitudinal crevasses would facilitate spreading of the ice about obstructing piles of drift and their being shaped into drumlins rather than their obliteration by erosion It might also induce localized deposition in piles or ridges which would later be shaped and might be added to by the plastering on of drift. Computations based on the ice stream forming the second set of drumlins show the radiation to have been even more marked than in the first case with corresponding greater crowding forward of the faster moving ice in the rear and more marked development of drumlins Comparison with segments of the glacier which had equal initial widths but did not form drumlins shows that in the latter there was very moderate radiation and that unless the ice in the rear was moving more slowly than in front there was a decrease in the volume of the stream as it advanced as opposed to the increase in volume of the spreading of the ice under its own weight and with no forward crowding of the ice in mass there would be absence of lateral stress and of the tendency to longitudinal crevassing, and this may explain the absence of drumlins Other factors than radiation are probably also involved

Prof Lawrence Martin of the University of Wisconsin, in a paper on "The Glaciers of Alaska" spoke in part as follows, Among the glaciers studied by the National Geographic Society's Alaskan expedition of 1910 are two of unusual activity. Columbia glacier, in Prince William Sound, Alaska, began to advance in 1908, and has been visited on July 15th, 1908, June 24th and August 22d, 1909, June 30th, and September 5th, 1910, during which time its front has been progressing at an undetermined rate where tidal, but on an island and at the borders at the rate of from 0 9 to 2.1 feet a day, destroying forests and peat bogs and modifying marginal drainage and marine deposits Childs glacier on Copper River was advancing at about its normal rate in August, 1909, the ice melting or discharging as icebergs into Copper River sufficiently fast so that the front remained nearly stationary During the winter of 1909-1910 the rate of motion increased, a previously stagnant, shrub-covered part of the margin visibly advancing into the forest at the rate of 2 to 8 feet a day during June to October, 1910 when it was re-mapped at frequent intervals Independently of this increased rate of advance the position of the ice front in the river has oscillated during the summer with the stages of water in Copper River A $1,400,000 steel bridge and the key to a railway system is threatened by this advance

The social side of these gatherings is not its least important, and there were many conferences among the guests which were held more or less in private, the subjects of which were not entered upon the programme

The Paleontological Society a daughter of the Geological Society held its meetings on the 28th and 29th of December They were attended by audiences that were highly satisfactory in point of number and as to personnel The papers delivered were decidedly technical in character and they covered a wide range of topics under the general subject of paleontology A second related society, the Association of American Geographers began its sessions on the 29th and kept many men in Pittsburgh during the remainder of the week The Association of State Geologists likewise held its annual meeting during the week

Thursday evening by invitation of the authorities of the Carnegie Institute the members of all three societies participated in an informal smoker at the Hotel Schenley at the close of the delivery of the presidential address by Dr Arnold Hague of the Geological Society

Wednesday evening was devoted to the annual dinner of the Geological Society, which was presided over at first by Dr Hague and was concluded under the leadership of Prof James F Kemp as toastmaster The reports of the officers showed a good condition of the society and there are many applicants for membership The society lost seven members by death during the past year and there are now 328 active members and 13 foreign correspondents. The election resulted in the choosing of Prof William M Davis of Harvard University as president, Prof William N Rice of Wesleyan University as vice president, Dr E O Hovey of the American Museum of Natural History as secretary Prof William Bullock Clark of Johns Hopkins University as treasurer, Mr J Stanley Brown of New York city as editor and Prof H P Cushing of Western Reserve University as librarian for the year 1911

The next meeting of the society is to be held at Washington D C in connection with the annual convention of the American Association for the Advancement of Science

---

The Light of the Sky

YNTEMA has made a series of investigations of the brightness of the sky which may be summarized as follows On some nights when there is no visible moon or aurora and the sun is more than 18 degrees below the horizon the sky whether clear or cloudy is distinctly luminous as a whole or in parts The brightness of the sky which usually increases toward the horizon is sometimes equal to that of the diffused light of the half moon Printed letters and the figures of a watch can be read with ease and comparatively small objects at considerable distances can be seen—telegraph poles more than 300 feet away for example If the sky on these nights is clear it appears white or pale blue so that the Milky Way can scarcely be distinguished On the other hand there are clear nights when the sky appears almost black

The brightness of the sky cannot be caused by the stars alone for in this case it would be the same every night and would not increase toward the horizon, but would rather be diminished there by atmospheric absorption The variation in the light of the sky suggests a terrestrial cause Only a very small fraction of the luminosity can be explained by dispersion of light in the atmosphere as is proved both by theory and by experiment Yntema assumes that the earth is always surrounded by an aurora, which illuminates the entire sky to a greater or less degree It is well known that the characteristic green line of the aurora often appears in the spectrum of the sky light even when no aurora is visible to the naked eye

Primitive Vaccination

THE November issue of Hygiela the circular of the International Hygienic Exhibition which is to be held in Dresden next year, states that vaccination or inoculation which is commonly regarded as a triumph of modern medical science has long been practised by the civilized races of Asia, and even by African and other savages probably as a result of Asiatic influence We first meet inoculation for smallpox among the Chinese Lockhart gives the following quotation from an old Chinese manuscript, which was probably written early in the 11th century The ancients possessed the knowledge of inoculation for smallpox. It has come down to us from the reign of Chin tsung of the Ting dynasty and was discovered by a philosopher When the disease breaks out spontaneously it is very serious and often fatal but when it is produced by inoculation it is usually mild and does not cause more than one death in ten thousand cases" In Persia inoculation is accomplished by scratching the forearm and rubbing into the slight wound after bleeding has ceased the pulverized scurf which falls from a smallpox patient The Ashantee negroes, according to Bowditch, inoculate in seven places on the arms and legs. The Moors practise the same method The Siamese have the peculiar custom of blowing the scurf into the nose An interesting collections of material illustrating this subject will be shown at the Dresden exhibition

An interesting sidelight on Chinese railways is contained in the report of Mr Pitzipios, British consul at Chingkiang A proposal was made to have a railway from Kuacheu, at the mouth of the Grand Canal, to Hsü Chou Fu Owing, however, to the indifference of the wealthy men of Yangchow and other places, the necessary capital could not be subscribed. One wealthy and influential Chinese gentleman of Chingkiang worked hard to secure funds, but met with rebuffs in all directions. Curiously enough, during the later months of 1909 a well-printed leaflet, bearing a rhyming song exhorting people to subscribe capital to build this railway, was freely distributed among the Chinese The gist of it was to the effect that the trade of Chingkiang would suffer by the completion of the Tientsin-Pukow Railway, and that the Kua-Hsü Railway was the only thing to save the situation. All were, therefore, urged to buy shares at $5 each, payable at the rate of $1.25 a year The exhortation included women and children, artisans, and coolies, and the present value of the Pekin-Hankow Railway shares was put forward as an incentive.

INDEX OF INVENTIONS

For which Letters Patent of the United States were Issued for the Week Ending January 10, 1911,

AND EACH BEARING THAT DATE

[See note at end of list about copies of these patents.]

Acetyl cellulose to enhance its elasticity and its power of absorption for dye stuffs, treatment of, E. Knoevenagel 981 574
Acid, apparatus for making sulfuric, R Moritz 981,108
Aerial apparatus, G M Fowler 981 180
Aeroplane, J A. Goodwin 981 430
Agitator, J A McCaskell 981 098
Air craft, F Brackett 981 367
Air pressure means for automatically producing and utilizing, Borger & Atkins 980 910
Alarm. See Burglar alarm
Alloy, W B Driver 981 542
Amusement device, L. W Fabel 980 984
Anastigmatic objective, C Graf 981 412
Animal trap, J Drubko 981 89
Antirattler and thill support, W N Thomas 981 142
Ash pan and detachable bail therefor, O J Mortenson 980 990
Automatic regulator, E C Newcomb 981,104
Automobile horn, O Braf et al 981 526
Autopiano key lock, W F Bayer 981 158
Bag filling machine, A M Bates 980 905
Bag filling machine valve, A M Bates 980,906
Bag frame, Hiering & Fuller 980 9[illegible]
Bait, Miller & Ball 981 454
Baking powder manufacture and production of, B Federer 980 930
Baling press, A L. Stephenson 981 401
Ball cage, Goodwin & House 981 551
Barrel finishing machine, R D Kinyon 980 907
Bearing, W J Drewer 981 065
Bearing, ball, L. Langhaar 981 577
Bearing, roller, O F Zahn 981 049
Bearings, ball holding cage for ball, R Mitner 980 982
Bed extension, F D Chappell 981 533
Belt, conveyer, T Robins 981 312
Belt, suspender, S Neill 981 406
Berry washing device, C E Loetzer 981 205
Bicycle lock, L. H Halwick 981 359
Binder reel, F Seibert 981 319
Binding post, electrical, W Hector 980 945
Bit, O Smith 981 488
Blower, boiler, Waller & Barnhill 981 146
Blowpipe, J F Williams 981 342
Boat attachment, A Kalous 980 964
Book, account, G B Edgar, Jr 981 548
Bookbinding backing for, Hager & Kunzl 981 534
Boring head, H Casler 981 06
Boring tool, R E Dette 981 392
Bottle cap, milk, O W Molfenter 981 457
Bottle closure, W O Schwartz 981 48[illegible]
Bottle filler, milk, I W Merriam 980 985
Bottle, non-refillable, R Debrenback 980 9[illegible]5
Bottle, non refillable, I Takacs 981 327
Bottle washing machine, J A Vince 981 002
Box strap, metallic, K C Cary 981 [illegible]32
Brewing fermented beverages, compound for use in, I Stein 981 3[illegible]
Brick machine, A H Olsen et al 981 210
Burglar alarm, explosive, E Reichenbach 981 308
Button making machine, F M Hopkins 981 564
Cabinet, clothing, M J Freeman 981 187
Camera and film package therefor, F E Cole 981 004
Can cover, J B Conover 981 384
Canoe, folding, A A Henrikson 981 191
Cap lifting and moving device, H F Hittner 980 9[illegible]1
Car coupling safety appliance, R F Crowley 981 067
Car dump, I Bateman 981 157
Car grain door, J Henry 981 084
Car grain door, J Archer 981 150
Car indicator, street, S W Chick 981 107
Car, railway, W J Spangler 981 131
Car register, street, Hudson & Smith 981 005
Car safety step, freight, A C Neale 981 40[illegible]
Car step, folding, C A Lathrop 981 203
Car wheel, C N Crouch 981 530
Car wheel guard, E E Hutchings 980 958
Car wheel making, J H Taylor 981 081
Car motor leads, connection for street, H Etheridge 981 545
Cars, steering mechanism for road freight, M J Todd 981 400
Carbureter, E. M Barker 981 1[illegible]0
Card button, A I Currier 981 547
Card for card systems, extension, F J Boyce 981 3[illegible]0
Carrier. See Feed and litter carrier
Carrier brake, overhead, A Gahlmann 981 070
Carrier track, W & J F Mitchell 981 400
Cart brake, logging, I J Knutson 981 68
Caster, furniture, B I Kenyon 980 965
Castings of precious metal, mold for, I W Swem 981 033
Cellulose films, continuous manufacture of, E. Brandenberger 981 368
Cement, bituminous paving, C Richardson 981 225
Chair fan attachment, A Rosenson 981 476
Channel flap laying machine, J B Hadaway 981 190
Checkrein attachment, H G Weatherill 981 506
Cheese handling apparatus, T Christoffel 981 481
Chuck, J A. Jarvis 981 066
Churn and butter worker, combined, R B Disbrow 981,[illegible]94
Chute, combination dipping and loading, C. F Townsend 981 530
Cigar banding machine, E I Sheldon 981,017
Circuit, loaded phantom, Campbell & Shaw 980 921
Circuit, phantomed loaded, T Shaw 981 045
Clevis, E. D Hobbs 981 427
Clothes line prop attachment, W H Billings 980 915
Clutch, H W Winter 981 345
Clutch, friction, H E Porter 981 000
Clutch, friction, I B Marfield 981 2[illegible]
Clutch, friction, J W Dearborn 981 350
Clutch mechanism, J M Schoonmaker Jr 981 010
Clutch mechanism for agricultural implements, I Willis 981 343
Clutch or clutch pulley rope, J M Boyd 981 525
Clutch shifting mechanism, F B Allen 980 897
Coasting device for purposes of amusement, L N Moss 981 462
Cock, ball, O H Jones 981 570
Coil retainer, rotor, Brown & Williamson 981 067

A printed copy of the specification and drawing of any patent in the foregoing list or any patent in print issued since October 4th 1859 will be furnished from this office for 10 cents provided the name and number of the patent desired and the date be given. Address Munn & Co. Inc. 361 Broadway New York.

Canadian patents may now be obtained by the inventors for any of the inventions named in the foregoing list For terms and further particulars address Munn & Co Inc 361 Broadway New York

Aeronautical Notes

The Winner of the Paris Brussels Race—Herr Wynmalen the Dutch aviator captured the $20 000 prize for his flight from Paris to Brussels and back with a passenger in less than 36 hours on October 16th and 17th 1910 Eleven attempts were made by leading aviators but with the exception of Wynmalen none was successful Legagneux with Martinet as passenger reached Brussels in record time on November 13th but he was unable to return to Paris on account of the heavy wind This was the second time he had made the flight one way

Death of France's Oldest Lady Aeronaut—Close upon the death of Octave Chanute in this country comes news of the death in France of her oldest woman aeronaut Mme Dozeville who recently died at the age of 7[illegible] years was a sister of Louis Godard the well known balloon and airship constructor From 1865 to 1867 the then Eugenie Godard made numerous free ascents with her brothers Eugene Louis and Jules and also a great number of parachute drops

The Coupe Fémina and Other French Prizes—The last day of the old year aviatress Jane Herveu the fifth French woman to receive an aeroplane pilot's license attempted to beat Helene Dutrieu's record of 105 miles in 2 3[illegible] made on December 21st last for the Coupe Fémina She only succeeded in flying 90 miles in 2 hours in her Blériot monoplane however—Lieut Cammerman is the winner of the Weiller military prize of $5 000 He flew 232 kilometers (144 15 miles) with a passenger in 4 03 04 on December 21st Lieut Caumont while trying a Nieuport monoplane before competing for this prize lost his life at Buc on December 30th The Duperdussin $5 000 cup for the quickest 100 kilometers (62 1 miles) flown with a passenger before the end of 1910 was won by Laurens on a R E P monoplane on December 21st His time was 1 16 05 which beats by 20 minutes Aubrun's record at Rheims and corresponds to an average speed of 48⅓ miles an hour

The Baron De Forest Prize—The prize of £4 000 given by Baron De Forest mentioned below was won by Thomas Sopwith by his flight on December 18th of 169 miles from the Isle of Sheppey England across the Channel to Beaumont, Belgium Sopwith had a favorable wind He crossed the Channel in record time and completed the flight in 3½ hours averaging about 50 miles an hour He used a Howard Wright biplane fitted with an eight cylinder E N V motor Later on December 22nd Cecil Grace flew across the Channel and back again in his own Farman type machine but lost his bearings and turned out to sea when within five miles of the English shore As his cap was picked up a fortnight later he undoubtedly perished

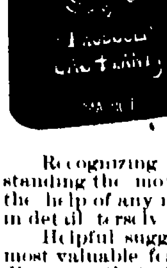
New Records for Michelin Trophy—On December 30th last Maurice Tabuteau won the French Michelin Trophy for 1910 by a flight lasting 7 48 31 3/5 in which he covered 363 46 miles Henry Farman attempted to beat this record the next day but he was unsuccessful He covered 302 6 miles in 7 hours 11 minutes time In England Capt Cody covered 185½ miles in 4 hours 47 minutes thereby winning the English Michelin Trophy and special prize In France four other attempts to win the Michelin Trophy were made upon December 31st Marie cov ered 329 miles in an R E P monoplane at Buc Breguet and Sommer flew 242½ and 109 miles on their respective biplanes while in the United States near New Orleans John B Moisant America's foremost aviator was pitched from his machine and killed when about to compete for the Michelin Trophy

Flight Across the Rio-de-la Plata—At Buenos Ayres on December 17th last Cattaneo succeeded in flying across the Rio-de la Plata a distance of 34 miles over the course followed The Italian aviator was 2 hours and 35 minutes making the passage owing to an extremely heavy head wind He eventually brought his Blériot safely to earth at Colonia and was awarded the $20 000 cash prize that had been put up for this flight—a flight much less difficult than that from Paris to Brussels and back with a passenger and for which a prize of the same amount (100 000 francs) was given Baron De Forest, of England also gave a prize of this amount for the English built aeroplane piloted by an Englishman that should fly across the Channel and travel the longest distance into Belgium before the end of the year 1910

The Wind and Aviation Above the Sahara—It has been asserted that one of the chief obstacles to flying above the Sahara desert for utilitarian purposes such as the carrying of mail and the like was the violence of the wind But on this point some very precise and almost conclusive information has recently been obtained by the National Aerial League of France This information comes from Capt. Boué chief of the geodetic brigade of the Tuniso-Tripolitan frontier During last October Capt Boué with the aid of a Daloz anemometer which the league presented to him observed the direction and velocity of the wind from Gabes to Djenefen going via Kethana Medonine and Tataouine During this month three entire days passed without any wind whatever and never except sometimes when there were gusts (only one of which showed a velocity of 20 meters per second—53¾ miles an hour—during two or three seconds) did the velocity of the wind exceed 12 meters per second (26¼ miles per hour) The daily average was but 4 4 meters per second (9 62 miles per hour) These observations are extremely encouraging since they show that apart from the single day perhaps when the sacred sirocco was blowing an aeroplane could easily have flown every day during at least eight hours out of twelve

According to the Railway Gazette the Prussian State Railways Administration has been moved apparently by a recent accident when signals were not observed to issue new orders regarding the inspection of signals Every year the officer in charge of trains the officer in charge of signals and an engineman selected for his experience and familiarity with the part of the line to be inspected are to go over the road on a locomotive but only two of them at a time on engines hauling trains They are to pay particular attention to the following points (A) The visibility of the signals—their background their obscuration by telegraph poles station buildings trees etc the effect on night signals of arc lights in the vicinity or the reflection of other signals, the condition of the signal glasses (B) The distance of the signal from the danger point (C) The grouping of signals where several stand near each other in one row or other wise the appearance of the signal from every position in succession the possibility of the confusion of signals (D) The substitution for signals standing left of the main track of signals on the right of the track (E) Substitution of high distant signals for low signals (F) Superfluous signals (G) The proper designation of main and branch tracks, where one post has several signals If all these points be attended to, the signaling installation should be all right

Modern Gas Engines and Producer Gas Plants



By R. E. Mathot, M. E.

8vo.; 314 pages, 152 illustrations; Price, $2.50 postpaid.

THIS is a practical treatise, setting forth the principles of gas engine and producer design the selection and installation of an engine, conditions of perfect operation producer gas engines and their possibilities, the care of gas engines and producer gas plants, with a chapter on volatile hydrocarbon and oil engines. A guide for the gas engine designer user and engineer in the construction selection purchase, installation operation and maintenance of gas engines.

Recognizing the need of a volume that would assist the gas engine user in thoroughly understanding the motor upon which he depends for power the author has discussed his subject without the help of any mathematics or theoretical explanations Every part of the gas engine is described in detail tersely clearly and with a thorough understanding of the requirements of the mechanic Helpful suggestions as to the purchase of an engine etc installation, care and operation form a most valuable feature of the work Each chapter is profusely illustrated with carefully prepared diagrams that elucidate the explanations of the text Thoroughly modern in the treatment of the subject the work discusses at considerable length the generation of producer gas and its utilization

What Electrochemistry is Accomplishing—I*

Modern Methods and their Results

By Joseph W Richards

My theme is to depict for you as clearly as I may be able the part which electrochemistry is playing in modern industrial processes I have no exhaustive catalogue of electrochemical processes to present nor columns of statistics of these industries but my object will be to classify the various activities of electrochemists and to analyze the scope of the electrochemical industries And since electrochemical industries have developed in almost all parts of the world except Pittsburg I will endeavor to bring to your view by means of pictures taken from actual photographs of plants in operation the reality of the large and important electrochemical industries

SCOPE OF ELECTROCHEMISTRY AND ELECTROMETALLURGY

Chemistry is the science which investigates the composition of substances and studies changes of composition and reactions of substances upon each other As an applied science it deals chiefly with the working over of crude natural material and its conversion into more valuable and more useful substances

Some common examples illustrate this statement are the conversion of native sulphur into sulphuric acid the manufacture of soda and hydrochloric acid from common salt the conversion of phosphate rock into superphosphate fertilizer etc etc Several pages would not suffice to merely catalogue the great variety of chemical industries immense amounts of capital are invested in them and they are some of the most fundamental industries in their relation to supplying the needs of a rapidly advancing civilization

Metallurgy is the art of extracting metals from their ores and of purifying or refining them to the quality required by the metal working industries It is a branch of applied chemistry The metallurgical industries form a highly important part of our national resources on them we depend for iron steel copper brass gold silver lead zinc aluminium etc in fact for all the supply of metals used in arts and industry

Electrochemistry is the art of applying electrical energy to facilitating the work of the chemist It is chemistry helped by electricity It is the use of a new agency in accomplishing chemical operations and it has not only succeeded in facilitating many of the most difficult and costly of chemical reactions but it has in many cases supplanted them by quick simple and direct methods it has even in many cases developed new reactions and produced new materials which are not otherwise capable of being made A few examples will illustrate these points Caustic soda and bleaching powder are made from common salt by a series of operations but the electrical method does this neatly and cheaply in practically one operation lime and carbon do not react by ordinary chemical processes but in the electric furnace they react at once to form the valuable and familiar calcium carbide carbon stays carbon except when the intense heat of the electric furnace converts it into artificial graphite The list of such operations is a long one and it may be said that the chemist has become a much more highly efficient and accomplished chemist since he became an electrochemist, and he is becoming more of an electrochemist daily

Electrometallurgy applies electric energy to facilitating the solution of the problems confronting the metallurgist Its birth is but recent yet it has rendered invaluable service It has made easy some of the most difficult extractions has produced several of the metals at a small fraction of their former cost and has put at our disposal in commercial quantities and at practicable prices metals which were formerly unknown or else mere chemical curiosities It has further refined many metals to a degree of purity not previously known The metallurgist is rapidly appreciating the possibilities of electrometallurgical methods and they already form a considerable proportion of present metallurgical practice

Applied electrochemistry covering in general all of the field just described is therefore an important part of chemistry and metallurgy and is rapidly increasing in importance It is a new art people are really only beginning to understand its principles and to appreciate its possibilities it is an art pursued by the most energetic and enterprising chemists with the assistance of the most skilled electricians Some of its most prominent exponents are electrical engineers who have been attracted by the vast possibilities opened up by these applications of electricity The chemists have worked with electricity like children with a new toy or a boy with a new machine they have had the novel experience of seeing what wonders their newly applied agency could accomplish and it is no exaggeration to say that they have astonished the world—and themselves

THE AGENTS OF ELECTROCHEMISTRY

The operating agent in electrochemistry is of course electric energy which may be used in three classes of apparatus viz

(I) Electrolytic Apparatus.
(II) Electric Arcs and Discharges in Gases
(III) Electric Furnaces

I Electrolytic Apparatus

Electrolytic apparatus and processes use or utilize the separating or decomposing power of the electric current Whenever an electric current is sent through a liquid material which is compound in its nature i e a chemical compound the current tends to decompose the compound into two constituents appearing respectively at the two points of contact of the electric conducting circuit with the liquid in question i e at the surface or face of contact of the undecomposable conducting part of the circuit with the decomposable part If the current has a definite direction the constituents appear at definite electrodes The action is simply the result of the current extracting or tending to extract) from the electrolyte *one of its constituents at each of the two electrode surfaces* All subsequent changes following upon this primary tendency of the current are called secondary reactions and are practically simultaneous with the primary These may even be regarded as truly primary reactions also the primitive decomposing or separating power of the current passing being regarded only as a *tendency* or a *determining* cause which practically results in the reactions actually taking place

This agency is an extremely vigorous and potent force for producing chemical transformations It enables us for instance to split up some of the strongest chemical compounds into their elementary constituents to convert cheap materials in short to perform easily some very difficult chemical operations and in some cases to perform chemical operations otherwise impossible A description of all these various processes would take a volume but a short explanation of a few of them will make the principles clear and suffice for my present purpose

Electrolysis of Water As a raw material water may be said to cost nothing Apply an electric current to it in the proper way and it is resolved into its constituent gases hydrogen and oxygen as cleanly and perfectly as anyone could desire These gases have many and various uses and are valued each at several cents per pound A whole industry has thus grown up based on the simple electrolysis of water to supply these two gases for various industrial uses. Europe possesses many of these plants there are a few in the United States The speaker has translated from the German a small treatise on this industry

Electrolysis of Salt Common salt sodium chloride is one of the cheapest of natural chemicals It has some uses of its own, but centuries ago chemists and even alchemists devised chemical processes for transforming it into other sodium salts, such as caustic soda or soda lye for use in soap soda ash or carbonate for washing or glassmaking and into chlorine bleaching materials Chemical works operating these rather complicated chemical processes exist on an immense scale in all civilized countries it is estimated that \$50 000 000 is thus invested in Great Britain alone The electrolytic alkali industry is barely twenty years old yet it is already more than holding its own with the older chemical process and advancing rapidly twenty years more will probably see the older processes entirely superseded—they are at present fighting for their existence As for the electrolytic process the salt is simply dissolved in water and by the action of the current converted into caustic soda at one electrode and chlorine gas at the other By some special devices these are kept separate and collected by them selves and the work is done The principles involved are simplicity itself as compared with the older chemical processes, the only agent consumed is electric energy and the products are clean and pure

Chlorates These are salts used on matches and in gunpowder Chlorate of potassium is a valuable salt with important uses It is made from common cheap potassium chloride, in solution in water, by simply electrolysing the solution without trying to separate the products forming at the electrodes. It is a simpler operation than the production of electrolytic alkali. Chlorate thus forms in the warm *solution and is obtained by letting the solution cool* and the chlorate crystallise out. The ordinary chemical manufacture of this salt was tedious and dangerous the electrolytic method has practically entirely superseded it.

Perchlorates These salts have more limited uses, but are made by expensive chemical methods. The electrolysis of a chlorate solution at a low temperature without separating the products formed at the two electrodes results in the direct and easy production of perchlorates I cite this more to illustrate what I might call the versatility of electrochemical methods rather than because of its commercial importance

Metallic Sodium The caustic soda produced from salt can itself be electrolytically decomposed this is the easiest way of producing metallic sodium. Sir Humphry Davy discovered sodium by electrolysing melted caustic soda and at this moment several large works are working this method on an immense scale The caustic contains sodium hydrogen and oxygen and the current simply liberates the sodium as a molten metal and frees the other two as gases, which escape into the air The process is simplicity itself—when the exact conditions are known and rigidly adhered to Metallic sodium is a very useful material to the chemist and the electrolytic method produces it at probably *one-fourth* the cost of *making it in* any purely chemical way

Magnesium This is a wonderfully light metal whose chief use is in flash-light powders Its compounds are abundant in nature but its manufacture by any other than the electrolytic method is almost impracticable The operation consists in simply passing the decomposing current through a fused magnesium salt—a chloride of magnesium and potassium found in abundance in Germany

Aluminium The most useful of the light metals an element more abundant in nature than iron yet which costs by chemical methods at least \$1 00 per pound to produce electrochemistry enables the makers to sell it at a profit at \$0 25 per pound. This is probably the most useful metal given to the world by electrochemistry Although the French chemist Deville obtained it by an electrolytic method in 1855 yet he had only the battery as a source of electric current and the process was too costly This very city of Pittsburg was the real cradle of the electrolytic manufacture of aluminium when in 1889 Mr Chas M Hall with the financial assistance of the Mellons and the business assistance of Capt A E Hunt commenced to work his process up at Thirty-third Street on the West Side The principle of the process is here again one of beautiful simplicity—when it is once made known Aluminium oxide abundant in nature is infusible in ordinary furnaces but easily melts and dissolves, like sugar in water in certain very stable and liquid fused salts—double fluorides of aluminium and the alkali metals On passing the electric current through this bath the dissolved aluminium oxide is decomposed appearing at the two electrodes as aluminium and oxygen respectively When all the oxide is thus broken up more is added and the operation continues One of the most difficult problems of ordinary chemistry is thus simply neatly and effectively solved by electrochemistry The lower cost of power at Niagara Falls drew the industry away from Pittsburg in 1893 and it is now run on an immense scale at several places where water power is cheap and abundant Mechanical power is however being produced cheaper every year gas engines have halved the cost of such power steam turbines on exhaust steam may even do better there is no inherent impossibility in the return of the aluminium industry to the Pittsburg district. Many other factors besides cost of power bear on the question cost of labor abundance of labor cost of carbon coal for heating various supplies railroad freights nearness to the consumers and many other considerations must be taken into account. Aluminium is certainly destined to become the most important metal next to iron and steel and as far as one can now foresee will always be produced electrochemically To have accomplished the establishment of this one single industry would itself have proved the usefulness of electrical methods and their importance to chemistry and metallurgy

Refining of Metals; Unless metals are of high purity they are usually of very little usefulness in electrolytic methods enable almost perfect purity to be easily attained and in addition permit the separation at the same time of the valuable gold and silver contained in small amount in the baser metals. These

* An address delivered at the Seventeenth General Meeting of the American Electrochemical Society in Pittsburg Pa. and printed in the Transactions of the Society

[illegible],000 000 worth of copper is electrically refined every year in the United States, the metal produced is purer than can be otherwise obtained giving the electrical engineer the highest grade of conducting metal, while several million dollars worth of gold and silver are recovered which would otherwise have to be allowed to remain in the copper Again the method is so simple that but a few words are necessary to set it forth in principle The impure copper is used as one electrode—the anode—in a solution of copper sulphate containing some sulphuric acid the receiving electrode—the cathode—is a thin sheet of pure copper or of lead greased The electric action causes pure copper only to deposit upon the cathode, if a properly regulated current is used while a corresponding amount of metal is dissolved from the anode Silver gold and platinum are undissolved and remain as mud or sediment in the bottom of the bath other impurities may go into the solution but are not deposited on the cathode if the current is kept low The cost of this operation is small and the results are so highly satisfactory that 90 per cent of all the copper produced is thus refined Similar methods are in use for refining other metals silver gold and lead are thus refined on a large scale antimony bismuth tin platinum zinc and even iron can be thus refined the field is very inviting to the experimenter and to the technologist and is rapidly increasing in industrial importance

Metal Plating All electro-plating is done by the use of electrolytic methods similar to those just described If we imagine the impure metal anode replaced by pure metal and the receiving cathode to be the object to be electro-plated we have before us the electro-plating bath ready for action Everybody knows the value and use of gold silver and nickel plating less well known are platinum cadmium chromium zinc brass and bronze plating These are among the oldest of the electrochemical industries Electrotyping is only a variation of this work also the electrolytic reproduction of medals engravings cuts etc and even the production of metallic articles of various and complicated forms such as tubes needles mirrors vases statues etc There is opportunity here to hardly more than catalogue these various branches of electrometallurgical activity Pittsburg people will be interested however in knowing that many of the newer buildings in this city contain thousands of feet of electrical conduits zinc plated in splendid fashion by electrolysis at a works within a few miles of this city At McKeesport tubes are coated by dipping into melted zinc on an immense scale but the electrolytic method is gaining a foothold and we may live to see all galvanizing in reality practised as it is spelled The removing of metallic tin from waste tin scrap is also accomplished on a large scale by the application of similar principles It is being operated at a distance from Pittsburg but your open hearth furnaces use up annually thousands of tons of the scrap steel thus cleaned and saved for remanufacture into useful shape

Without having mentioned or described more than a fraction of the electrolytic methods in actual industrial use I hope that I have made clear the importance and extent of this kind of electrochemical processes Assuming this we will pass to the consideration of another entirely different and yet important class of apparatus and processes

II Electric Arcs and Discharges in Gases

Electric arcs and high tension discharges through gases are capable of producing some chemical compositions and decompositions which are very useful and profitable to operate This is a branch of electrochemistry which has not been as thoroughly studied as some others its phenomena are not as thoroughly under control as electrolysis and electro-thermal reactions and its possibilities are not as thoroughly understood or utilized

Ozone is being made from air by the silent discharge of high tension electric current The apparatus is so far simplified as to be made in small units suitable for household use ready to attach to a low tension alternating current supply The uses for the ozone thus produced are particularly for purifying water and air it makes very impure water perfectly safe to drink and purifies the air of assembly halls and sick rooms acting as an antiseptic According to all appearances this electrochemical doubling up of oxygen into a more efficient oxidizing form is developing into a simple and highly efficient aid to healthy living

Nitric Acid is an expensive acid made from the natural alkaline nitrate salts such as Chili saltpeter These nitrates are the salvation of the agriculturist for they furnish the ground with the necessary nitrogen which plants can assimilate The Chili nitrate kings have gained many millions of dollars even hundreds of millions in thus supplying the world's demand for fertilizer But electrochemistry has another solution to this problem which is rapidly rendering every country which adopts it independent of the foreign fertilizer The air we breathe contains uncombined nitrogen and oxygen gases which if combined and brought into contact with water furnish the exact constituents of nitric acid The way to do this has been laboriously worked out and the electric arc is the agent which does it Air is simply blown into the electric arc where it for an instant partakes of the enormous temperature and on leaving the arc is cooled as quickly as possible In the arc the combination of nitrogen and oxygen is effected to a certain extent and the mixture is cooled so suddenly that it does not find time to disunite The nitrogen oxides thus obtained are drawn through water and this solution of nitric acid is run upon soda to produce sodium nitrate or on lime to produce calcium nitrate the latter called nitro lime or Norwegian saltpeter These salts entirely replace the South American natural salt

The materials used in this industry are air and lime and to these is added electrical energy Air is universal lime cheap almost everywhere and electrical energy is cheapest where water powers are most abundant In Norway water power can be developed and electrical energy supplied from it at a total cost of $4 00 to $8 00 per horse power year Some other countries can do nearly as well Under these conditions almost every country can afford to make its own nitrates and so be independent of other countries for the fertilizer needed in peace and the gunpowder used in war Norway felicitates itself already on being thus independent nearly 200 000 horse power is being utilized there by a $1[illegible] 000 000 syndicate and the industry is spreading rapidly over Europe The study of this problem its solution and the rapid development of this vigorous industry is one of the most remarkable chapters in the history of recent industrial development In this accomplishment electrochemistry has signally aided the agriculturist and demonstrably multiplied the food supply resources of all civilized and highly populated countries

Boron is an element which has until recently defied the best efforts of chemists to isolate in a pure state It is an element which may have important application in the manufacture of a high class special steel—boron steel Dr Weintraub one of our fellow members has recently solved the problem of its production by an adaptation of the oxygen nitrogen arc apparatus and utilizing the same principle of introducing the material into the arc and very rapidly cooling the products obtained We mention this not because of its great commercial importance at present but because it shows how the arc method may be of wide application in solving other difficult chemical problems It has opened before us a new method in chemical science and may give birth to many and various new chemical industries

(To be continued)

The Question of Exercise

WHY should men whose natural physical endowment was always above par and who have been famous for their powers—gridiron stars crack oars men sturdy tug o wars men record makers in field sports—succumb to maladies which their weaker brothers readily conquer? It cannot be fairly assumed that the type of disease was so much graver in their cases We must look to other causes than this and the heart tells us why That organ had long been overtaxed and had after years of strenuous physical effort become abnormally large and in turn become degenerate so that it could no longer be relied upon to fight a battle which it might safely have waged without the previous strain

This entire question is ably considered by Dr Albert E Sterne in his presidential address before the Ohio Valley Medical Association

During the developmental years he tells us the comparative demand made upon the heart is pretty well up to its limits all of the time for with body growth there is constantly increasing tissue formation This new tissue requires nourishment and this can be conveyed only through the circulation After what we term full growth has been reached there is relatively and actually less strain placed upon the heart so that it can more readily respond to any unusual yet reasonable demand made upon its power During the years of adolescence however while the heart is being taxed to its capacity most of the time it cannot be safely asked to do too strenuous service The growing boy or girl who complains of shortness of breath pain in the side and palpitation upon moderate or prolonged effort instances this dictum clearly Examples of this kind are so common as to require only the merest mention After the developmental period such phenomena become less frequent, even though the demand upon heart and blood vessels be considerably greater

"By means of accurate apparatus the tension to which the circulation is subjected can be measured and any increase or decrease from the normal be registered. Increase in tension, that is, force for the heart and elasticity for the arteries, means increased muscular effort and expenditure on the part of the heart. This the organ can safely give, if the demand [illegible] too great or too constant; but only then, for it must be remembered that the heart is a muscle—indeed a very powerful one and like every other muscle it adds to its intrinsic volume through use that is it becomes enlarged Once this condition becomes established the heart continues to exert undue force automatically and drives the blood too vigorously against the arterial walls to the lasting detriment of the latter which striving to maintain their normal compensatory relationship increase their own muscular coat and herewith is established an abnormal condition a true pathology a real vicious cycle Even in minor degree such a condition cannot be regarded lightly as baneful effects in after life are pretty sure to follow Lowered resistance and lessened vitality are pretty certain sequelæ In the major degrees the effects are really disastrous Here we see often excessive idiopathic hypertrophy or essential heart enlargement due wholly to the constant strain which had been placed upon that organ either at a period when it had all it could reasonably do to fulfill its normal duty or after this period has been passed by whipping it to activity beyond its potential capacity Sooner or later every hypertrophic muscle undergoes degeneration and every hypertrophic heart does the same thing Yet even if it did not the loss of elasticity of the arterial walls—the vital rubber of body tissue—would alone bring about general inanition

Purely on medical grounds therefore I am opposed to such forms of exercise for growing boys and girls especially In my opinion strenuous sports or athletics of every description which place an abnormal demand upon the circulation cannot be too emphatically condemned They should have no place at all in our grade schools intermediate or high schools public or private and be permitted only under rigid physical scrutiny even in the undergraduate classes of higher institutions of learning associations clubs or whatever they be called where the participants are not practically full grown and developed beyond the average.

In almost all of our universities and colleges medical oversight of all aspirants to athletic honors is given This is probably true also of some of our preparatory, private, and less frequently public schools But is this true of even a respectable minority? Moreover, this lack of scrutiny by competent medical authority is most apparent just where it is most essential for the growing and half grown boys and girls

Of all athletic sports doubtless football makes the greatest and most constant physical demand In minor schools it should be forbidden not merely because of accidents but chiefly because it is a sport for no weakling even though grown Football is a man's game in every sense and then only for men above physical par What what I have stated in regard to football is true I feel experience will substantiate It is a notable fact that men of powerful physique naturally who have been in their day famous athletes show a remarkable lack of resistance in later life and frequently become victims of diseases which they should have been expected safely to weather Instances of this sort have not been isolated Indeed they have occurred frequently enough to ask the reason

The Propagation of the Sound of Explosion

SOURCES of sound of great intensity are immediately surrounded by a region of normal audibility of irregular extent which is surrounded by a much larger region of abnormal audibility which in certain cases which have recently been investigated is separated from the inner region by a silent zone some 60 miles in width G von dem Borne offers the following explanation of these phenomena

In the lower strata of the atmosphere where the temperature decreases in ascending and the molecular weight of the air is sensibly constant the acoustic rays are concave above In the upper strata on the contrary they are concave below because of the greater proportion of light gases of small molecular weight in the atmosphere and the consequent increase in the velocity of sound The wind exerts only a secondary effect upon the phenomena The calculations of this scientist agree so well with the facts that the hypotheses upon which they are based particularly in regard to the composition of the air at different heights must be considered as expressing the essential truth A more profound study of the phenomenon in the case of volcanic eruptions for example might give valuable information concerning the temperature of the upper air to a height of about 60 miles and the proportions of various gases in the atmosphere

The Manufacture of Rolled "H" Beams*

A Review of Recent Practice

By G E Moore MIME

MANY inv n o s hav devo ed time and brain work to the f of he eans for man fact ring rolled beams a f a er y ars nore par icularly to the man fa ure of so a led H beams or beams hav ng flanges of great width as compared with the

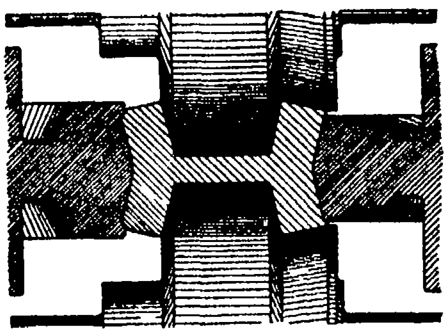

FIG 1 R HIN R LLS OPEN

height of the beam With ord nary tw or three high mills having grooved horizontal rolls only the practi cal economic limit appears to have been reached n the case of the commercial standard sections but beams of much larger section than these and more particularly beams having relatively far wider flanges are rolled more or less successively in universal mills

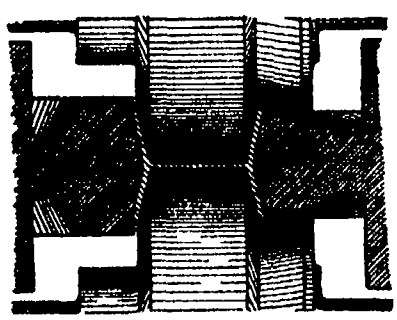

FIG 2—ROUGHING ROLLS CLOSED

which have both horizontal and vertical rolls Moreover with a universal mill a more economic distribu tion and better working up of the metal appears to be attainable than is the case with ordinary grooved rolls Using grooved rolls only the width of flanges which it is possible to roll is limited not only by the necessity of using rolls of very large diameter to ac

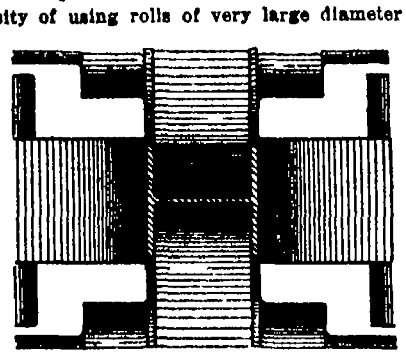

FIG —FINISHING ROLLS

commodate the deep grooves necessary to produce wide flanges and still leave sufficient metal in the rolls to give the necessary strength thereto but also by the necessity of making such grooves with a very great inclination of their sides in order to avoid the tend ency for the metal to become jammed therein which

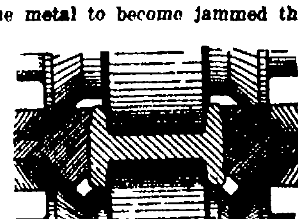

FIG 4 TWO HIGH ROLLS OPEN

results in the flanges being weakened if not torn away altogether

Universal mills aving a pair of horizontal and a pair of vertical rolls all in the same vertical plane are now in operation adapted to roll beams of much larger sizes than hitherto called for or say up o about 30 inches high by 15 inches wide But the prac-

tical difficulties which had to be overcome to insure success in the production of such sections has neces sarily involved a complication of the machinery used as compared with the mills customarily used to roll ordinary standard sections

The difficulty of working up the metal in a compli cated section such as an H beam undoubtedly is is

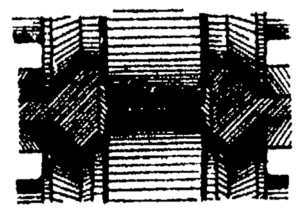

FIG 5 TW HIGH ROLLS CL SED

to secure sufficient uniformity to avoid undue internal stresses having regard to the comparative thinness of he metal in the web and flange necessary to enable them to be manufactured sufficiently cheaply to com pete commercially with built up beams Another dif ficulty is that of produ ing finished beams of suf ficiently good appearan e free from fins eccentricity of web and other irregularities These are the chief

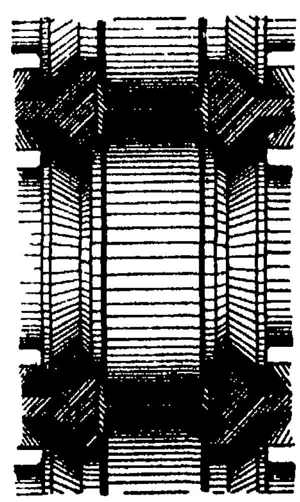

FIG 6—THREE HIGH ROLLS

points which the inventor has had to watch and to overcome which still taxes his ingenuity

In what follows the author proposes first to describe briefly a few of the characteristic types of machines disclosed by different inventors through the medium of the Patent Office of the United States of America, to offer a few remarks thereon and finally to present his own suggestions for criticism

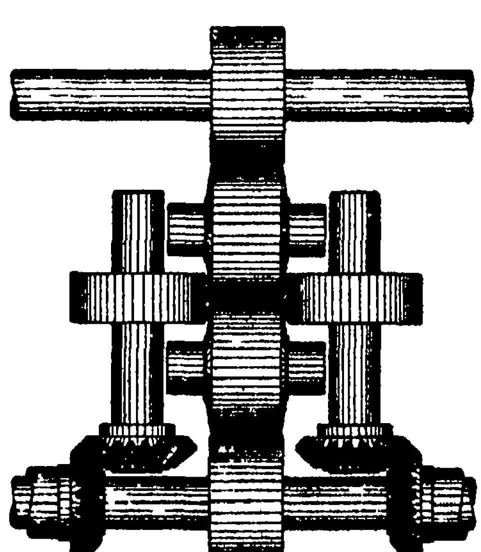

FIG 7—FIRST MILL

H Sack patent No 365100 (1887) describes a single reversing universal mill having a pair of hori zontal rolls and a pair of vertical rolls with their axes all lying in one vertical plane the two horizontal rolls being both alike but individually unsymmetrical, while the two vertical rolls are both different but in dividually symmetrical—Figs 1 and 2. Thus the gaps between the rolls are on one side at the extreme out-

side edges of the flanges and on the other side, at the extreme inside edges of the flanges. After each pass between the rolls the bar is tilted half round, and the positions of the flange edges relatively to the po-

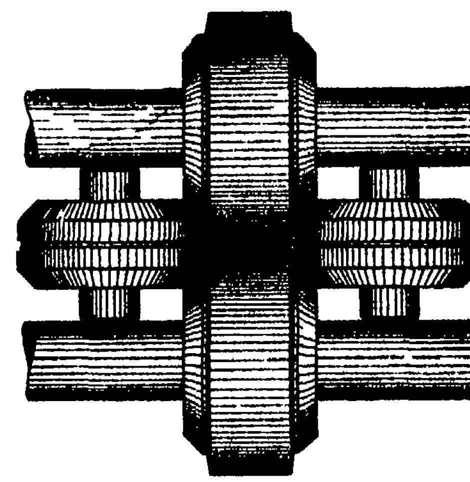

FIG 8—SECOND MILL

sition of the gaps between the rolls are reversed, and the edges which in one pass were adjacent to the gaps between the rolls are in the subsequent pass adjacent to the closed corners of the rolls In this way the surplus metal extr ded between the gaps of the rolls in one pass is rolled down and suppressed in the next.

The use of a single set of rolls for the reduction of the preliminary bar into a beam renders reversing and adjustment of the rolls after each pass necessary and it is impracticable with the rolls as described by H Sack and illustrated to have a closed pass between them At best gaps are left at the corners of the flanges which gradually become narrower as the pass is reduced and the blank rolled down until the

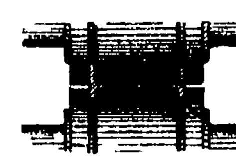

FIG 9 THIRD MILL

final adjustment is made prior to the final reduction when the gaps are reduced to a minimum Nor even at the final pass is it practicable to have an entirely closed pass because although the rolls may be ad justed prior to the final reduction so that they touch and the pass is practically closed, yet directly the bar enters the pass deflection takes place which opens out the pass and gaps are left between the rolls where fins will be formed on the bar

With this method the section is developed with flanges outwardly bent from the longitudinal center line in order to obtain a better rolling effect with the horizontal rolls upon the flanges and this feature ren ders necessary the use of a finishing set of rolls—Fig 3—through which the bar is passed after having been completely reduced in the previous set. The pass be tween these rolls need not be adjustable excepting to

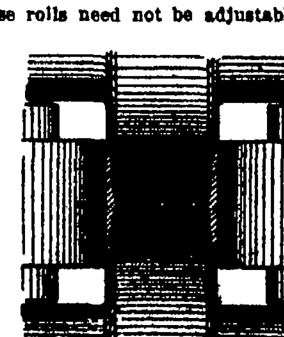

FIG 10—SINGLE REVERSING UNIVERSAL MILL

compensate for wear or displacement, and may be fixed in the ordinary way Its shape is exactly that of the section required so that the effect of passing the bar through these rolls is merely to square up the flanges and give a final finish to the bar particularly at the corners of the flanges, where traces of surplus blank metal may have been left after reduction in the previ ous mill. No appreciable reduction need be given to

* Iron and Steel Institute.

[illegible] the finishing rolls and, consequently, no [illegible] deflection of the rolls takes place when the bar is passed through them the pass, therefore remains practically closed and the formation of fins on the finished bar is avoided

J. [illegible] patent No 400 495 (1889) describes a single reversing universal mill having a pair of horizontal rolls and a pair of vertical rolls with their axes all lying in one vertical plane the two horizontal rolls being unlike each other but individually symmetrical, while two vertical rollers are both alike but individually unsymmetrical—Figs 4 and 5 Thus as in the [illegible] mill the positions of the flange edges are changed relatively to the gaps between the rolls by tilting the bar half round after each pass and thereby rolling down in one pass the surplus metal extruded between the gaps in the rolls in the previous pass. Or he proposes to attain the same result

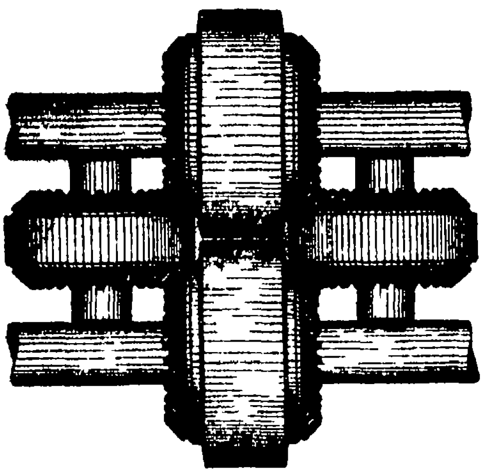

Fig 11 —NON REVERSING UNIVERSAL MILL

without tilting by using a three-high universal mill having rolls of exactly similar construction to those described above but with the top and bottom rolls alike and the center roll different—Fig 6

In this mill the bar is developed with straight flanges lying in a plane at right angles to the web so that no subsequent straightening is required and the bar may be finished in the one mill only

J Kennedy and H Aiken patent No 410 107 (1889) describe a series of mills comprising three different types each having a function distinct from that of the others

The first is a reversing roughing universal mill having adjustable horizontal and vertical rolls with their axes all lying in one vertical plane—Fig 7 In this it is proposed to reduce the ingot or bloom into approximately the finished form of beam required by passing it several times backward and forward through the rolls and adjusting the last together after each pass When the bar emerges finally from the mill the sides and edges of the flanges are still

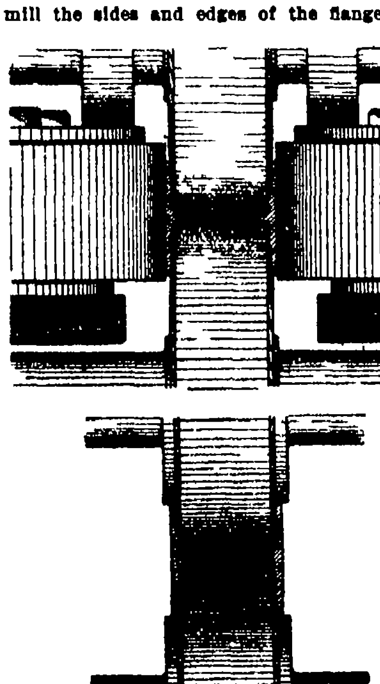

Fig 12 —REVERSING UNIVERSAL MILL

rough and it has consequently to undergo a further operation in the next mill

The second mill—Fig 8—is a non reversing universal mill having non-adjustable horizontal and vertical rolls with their axes all lying in one vertical plane, and intended to reduce the sides of the flanges only. It is proposed to pass the bar through these once, and in order to secure effective co-operation between these and the subsequent rolls and to prevent the formation of fins it is proposed to roll slight depressions in the center of each flange which the next operation will obliterate

The third mill is a non reversing two-high mill having non adjustable horizontal rolls only intended only to reduce the edges of the flanges—Fig 9 It is proposed to pass the bar through them once to bring it to its finished form and to shape the edges whereby the slight depressions formed along the center of the flanges in the previous mill will be exactly filled in this operation and no fins will be left on the finished bar

L D York patent No 410 724 (1889) covers a

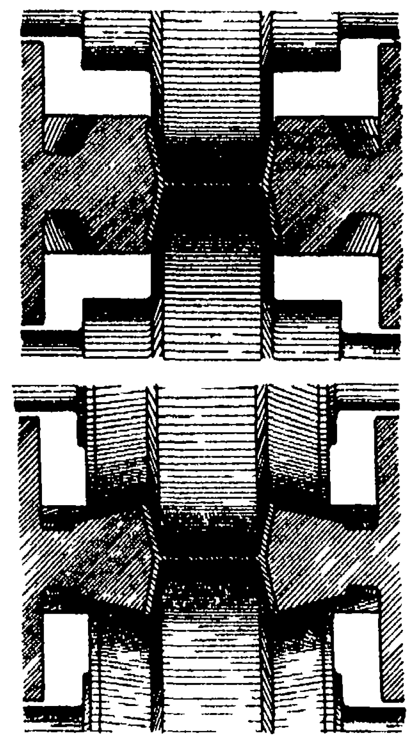

Fig 13 —TWO MILLS ARRANGED SIDE BY SIDE

single reversing universal mill having a pair of horizontal rolls and a pair of vertical rolls with their axes all lying in one vertical plane the horizontal rolls being both alike and symmetrical and the two vertical rolls similarly both alike and symmetrical—Fig 10 It does not transpire how the formation of fins is avoided but some supplemental means would be required as gaps must necessarily occur between the rolls until they have been adjusted to their ultimate positions prior to the final pass and fins would inevitably be formed on the edges of the flanges of the bar

E M Butz patent No 499 651 (1893) describes a series of non reversing universal mills each having a pair of horizontal rolls and a pair of vertical rolls with their axes all lying in one vertical plane the two horizontal rolls being alike and symmetrical and the two vertical rolls being similarly alike and symmetrical—Fig 11 The rolls are non-adjustable having a fixed pass and the bloom is reduced by passing it once only through each set of rolls the pass of which is narrower in each set than in the preceding set until in the last set of rolls the pass has the exact contour of the finished beam Thus as many mills must be used as number of passes necessary to reduce a bloom into a finished beam each mill having its rolls shaped according to the reduction required to be given in each pass

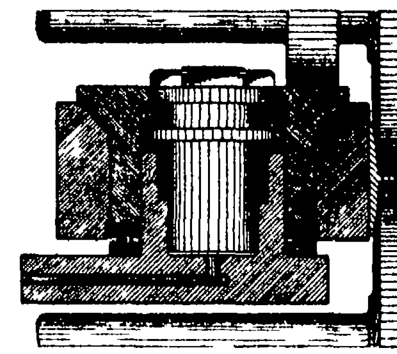

Fig 14 CONTACT BETWEEN ROLLS BY HYDRAULIC PRESSURE

The rolls being fixed and the adjacent surfaces of the horizontal and vertical rolls being suitably shaped so that they are almost in contact with each other it is probable that no very pronounced fins will be formed on the bar but as it is not practicable to close the gaps between the rolls particularly as during rolling considerable deflection takes place and the pass somewhat opens out it is certain that at least beads if not fins would be formed on the corners of the bar flanges Consequently to obviate this Butz proposes to use supplementary means to roll down the corners of the beam flanges adjacent to the gaps between the rolls These consist of two small idle rollers one on each side of the beam as it emerges from the main rolls as shown dotted on the sketch—Fig 11—and so adjusted that at each successive rolling operation the pass between the main rolls would be only just filled up at those corners and there would not be sufficient metal to flow into the gaps and form fins It ap-

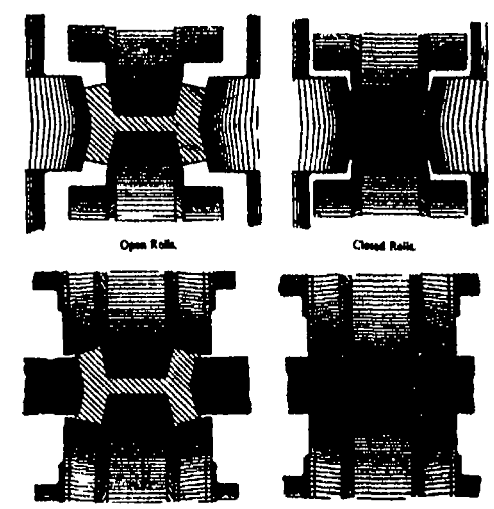

Fig 15 —PRIMARY FOUR ROLL REVERSING UNIVERSAL MILL

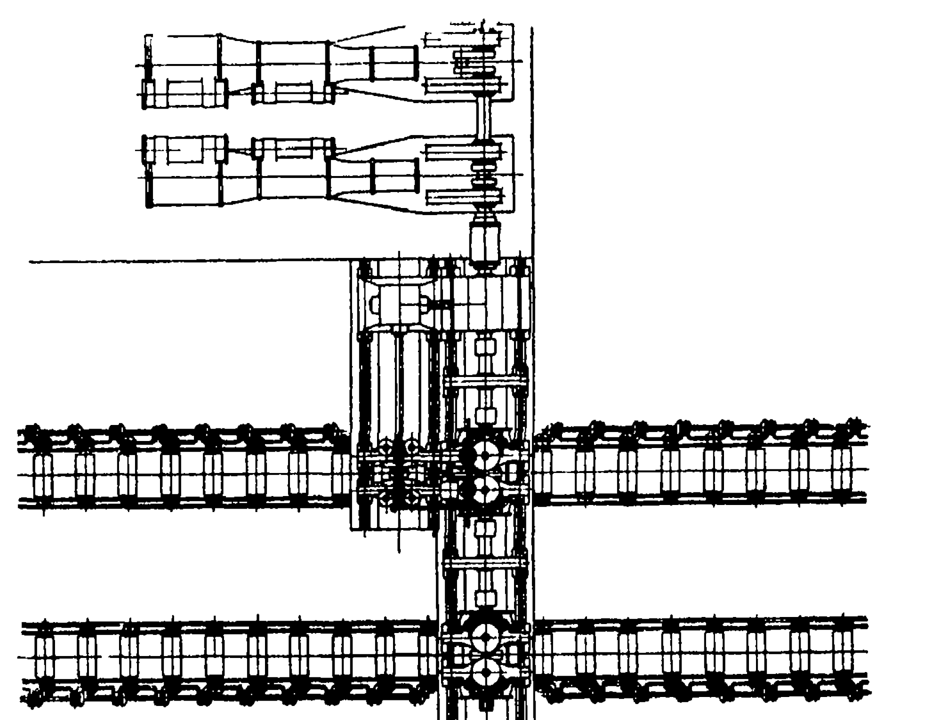

Fig 16 —TANDEM SYSTEM OF ROLLING UNINTERRUPTEDLY BACKWARD AND FORWARD

pears however as if this arrangement would necessitate some means of supporting the flanges as otherwise they would become bent and consequently the corners would not be rolled down in the manner intended

H Grey patent No 587 958 (1897) describes a reversing universal mill having a pair of horizontal rolls and a pair of vertical rolls with their axes all lying in one vertical plane the two horizontal rolls being alike and symmetrical and the two vertical rolls being similarly alike and symmetrical—Fig 12 This mill works in combination with a second mill having a pair of symmetrical horizontal rolls only The first mill has rolls for shaping the web and sides of the flanges of the beam but not the edges of the flanges and the second mill has rolls for shaping the edges of the flanges only

The two mills are situated as close together as possible and have their driving and adjusting mechanisms connected together so that the bar passes through both sets of rolls as nearly simultaneously as possible with such an arrangement Thus on one portion of the bar the flanges are being shaped on their edges while a short distance farther on the sides of the flanges and the web are being formed and the resulting beam is free from fins and presents a good appearance

The foregoing systems of rolling beams devised by different inventors have been chosen as typical and to illustrate the means which experience teaches or ingenuity suggests might be adopted to overcome the chief difficulties which were mentioned at the beginning of this paper each pointing out the direction in which the endeavors of the inventor were brought to bear and each possessing features which although involving complications as compared with the ideally simple plant represented by a pair of horizontal grooved rolls yet to be considered for the time being at least as having their justification in the better quality of the product obtainable thereby or in the ease cheapness or speed of production

The author does not assume of course that the systems he has chosen for his illustrations were all intended by their several inventors as means for manufacturing H or wide-flanged beams as differentiated from I beams or beams of the ordinary standard sections but they illustrate some of the features which the practical designer of to-day is likely to take into consideration in evolving a mill suitable for the production of H or wide flanged beams

For the production of beams with abnormally wide flanges in short H beams it may be assumed that a universal mill having four rolls—two horizontal and two vertical—all lying in one vertical plane is the simplest type of machine that can satisfactorily answer the purpose A single reversing universal mill requiring a tilting gear on each side with which the bar is turned half round after each pass is described by H Sack and also by J S Seaman These mills look simple but evidently have drawbacks due partly to the introduction of the tilting gears which are complications in themselves and are apt to require considerable time for their manipulation particularly when the beam is long and bent and partly also perhaps to the unsymmetrical section developed at each pass which in the rolls described by H Sack would have the tendency to produce a bar bent sideways and in those described by J S Seaman a bar bent vertically so that very powerful guides would be required in the case of the heavier beams to keep the bar sufficiently straight as it emerges from the rolls to enable the tilting gears to operate satisfactorily Briefly in other words the unsymmetrical rolls probably render other complications necessary in order to counteract their bending effect.

A three-high universal mill housed within one pair of stands only and requiring a lifting table on each side is described by J S Seaman—Fig 6—and this would doubtless be a simple system to adopt if it were practicable to design the details of the roll satisfactorily and simply as regards the accommodation and adjustment of the vertical rolls in particular Hitherto the author has not discovered a design of such an arrangement which would be considered satisfactory by him self or by the practical man

Two mills arranged side by side and having rolls such as those of H Sack or by J S Seaman could be adopted and tilting avoided by making the horizontal rolls and the vertical rolls symmetrical in each case but so formed that in one mill the edges of the flanges would be formed by the horizontal rolls only and in the other mill by the vertical rolls only—Fig 13

Then after each pass the bar could be shifted from the one mill to the other being rolled alternately in each mill until completely reduced By this means the formation of fins would be avoided but the plant would be considerably complicated and as the centers of the passes in the rolls of the two mills could not conveniently be arranged very close together the shifting gears would require to be particularly powerful and quick-acting in order not to lose much time over this operation

A plurality of mills having universal rolls or horizontal rolls only each mill intended for developing a certain portion of the section, is described by J Kennedy and H Aiken and also by H Grey but whereas the former leave certain portions of the section to take care of themselves in the initial passes and to be worked upon in the final stages only H Grey works upon the whole section at every pass and his system appears to possess advantages and to combine practicability and simplicity to a greater extent than the other systems hitherto described

Finally a series of universal mills each working upon the whole section of the bar but each adapted for one pass only is described by E M Butz This system would entail perhaps the maximum outlay on plant and machinery and would possibly be adapted for the maximum production per unit of time For rolling rails of which thousands of tons of one section can be disposed of on a single contract, a plant of this description might possibly be a good investment but for the manufacture of beams it seems more than doubtful whether it would be profitable to roll a sufficient quantity of each section to justify the expense of the plant and the time and trouble involved in changing so many sets of rolls for each section of beam

Having dealt at some length with the various means adopted to overcome or prevent the formation of fins which has been shown to be a matter of great importance calculated to influence enormously the design of the rolls of the mill containing such rolls and even of the disposition of the whole plant some mention should be made of the other features of the designs illustrated for which they have also been specially selected

J S Seaman J Kennedy and H Aiken E M Butz and H Grey have all endeavored to devise means for driving all the rolls of their universal mills whereas H Sack and L D York make no attempt to drive the vertical rolls but content themselves with driving both the horizontal rolls and letting the vertical rolls rotate by contact with the moving bar as it is drawn through the pass by the driven horizontal rolls

J S Seaman shows conical surfaces on the horizontal rolls engaging conical surfaces on the vertical rolls contact being maintained between the two rolling surfaces by the pressure of the bar as it is squeezed between the rolls This design has such grave defects that it cannot be regarded as mechanically sound enough for practical purposes for to be effective and avoid excessive wear and tear the sides of the conical surfaces should be at such angles that if prolonged the apices of the cones represented by the prolonged sides would meet at the centers of the respective rolls thus maintaining equal peripheral speed throughout the adjoining surfaces in the same way as bevel gearing is designed This is so obvious that it needs no further illustration but if the vertical rolls were so designed their conical surfaces would make such acute angles that they would have a powerful wedge action and on application of the rolling pressure component forces of excessive magnitude would occur resulting in excessive deflection of the rolls wear and tear and probably a wrecked mill

H Grey shows a device whereby conical or cylindrical collars on the top horizontal roll engage by frictional contact with conical or flat surfaces on the vertical rolls by such means must be so limited as two by means of hydraulic pressure—Fig 14 Like J S Seaman's design this has also the defect that the peripheral speeds of the frictional surfaces are not constant throughout and this defect cannot be remedied without introducing others as great or greater Moreover the driving force imparted to the vertical rolls by such means must be so limited as to render it inoperative for practical purposes Altogether the device looks too unsound mechanically for practical purposes

J Kennedy and H Aiken in their second mill show in contact conical surfaces which are designed on proper lines but between which effective contact could hardly be maintained during rolling for the pressure would cause deflection and spreading of the rolls nor could sufficient pressure be applied in any case to render such contact very effective They suggest however that the friction cones could be replaced by toothed gearing and similar toothed gearing is also suggested by E M Butz but in both cases, although a positive drive would be obtained it would not be possible to adjust the rolls even slightly without interfering with the proper engagement of the gearing

The neatest device for driving all four rolls while still maintaining adequate adjustment between them is that shown in the first mill by J Kennedy and H Aiken In this case the rolling pressure on the horizontal rolls is directly utilized to furnish pressure to give the requisite frictional contact between the driven and the idle horizontal rolls while the vertical rolls are positively driven by gearing Such a device would doubtless give satisfactory practical results but it is doubtful whether the results obtained would compensate for the complications which it involved in the mechanism of the mill.

In the manufacture of 'H' beams a bloom is usually first reduced in a blooming mill to a rough form and thereafter operated upon and finished in the universal mill and the idea that it is necessary to drive the vertical rolls in the universal mill as well as the horizontal rolls appears to be more theoretical than real

The advantage of driving the vertical rolls instead of letting them run idle is most apparent before the bar has been gripped by the rolls as it enters the pass and it is then conceivable that it would be easier to grip the bar if the vertical rolls were driven Once the bar has been gripped by the driven horizontal rolls there is however no apparent drag upon it due to any lagging of the vertical rolls In fact, if a tendency for the vertical rolls to lag behind were present no frictional device on the lines of any of those disclosed would be sufficiently powerful appreciably to diminish such a dragging effect

The best conceivable frictional device for driving the idle vertical rolls is afforded as soon as the bar has been gripped by the rolling surfaces of the horizontal rolls and is in contact with those of the vertical rolls and as before stated an independent frictional drive could only serve a useful purpose providing it were sufficiently powerful by helping to introduce the bar within the pass before it had been gripped by the horizontal rolls but not otherwise

In this connection the fact must not be overlooked that the horizontal rolls do not operate upon the web of the beam alone but operate equally upon the sides and perhaps also upon the edges of the flanges Thus it is not a case of the flanges being pulled through the rolls by a force imparted to the web but as a matter of fact the flanges are directly gripped by the driven horizontal rolls and the vertical rolls are only a form of surface for resisting the side pressure and participate in squeezing the bar and have really no appreciable tendency to slip and lag behind It is obvious however that the horizontal rolls will have a better grip upon the flanges the more the inside faces of these are inclined outwardly and the greater the inclination the greater will be the rolling effect also Consequently the author ventures to express the opinion that the method described by H Sack whereby the section is developed with the flanges outwardly bent from the horizontal center line is not only peculiarly well adapted for rolling H beams having very wide flanges but the material in such beams should also be particularly well worked up and free from internal stresses

The modern tendency is to reduce the inclination of the flanges of beams in order that the material may be better distributed by concentrating it as little as possible in the center of the section and distributing it more outwards in order to obtain a higher moment of inertia and thereby greater strength for a given weight This applies particularly to H beams intended to be used as columns where the least moment of inertia must be used as a basis for calculating their resistance against buckling and where the ideal section should have an equal moment of inertia in all directions

Therefore by so distributing the material in the flanges that a greater amount than formerly is concentrated on the edges of the flanges and a proportionately lesser amount at the roots where they join the web the moment of inertia is increased without increasing the weight of the beam

Now with the system described by H Sack the flanges can just as easily be made parallel throughout, or without any taper as otherwise thus obtaining the advantage of increased strength without adding to the weight of the beam But in addition to this advantage such beams possess the further advantage that they can be drilled and punched rivet and bolt heads bedded and connections with other members made much more easily and cheaply than the ordinary sections having flanges which taper however slightly These advantages are, moreover, obtained without sacrificing in any way the quality of the materials but rather the contrary is the case.

With all systems in which the flanges are developed straight—that is to say with their outside surfaces at right angles to the plane of the web or nearly so—a certain inclination of the inside surfaces is essential to the proper performance of the rolling or reducing operations and the more the taper is reduced the greater will be the risk of damaging the material by reason of the greater tendency of the sides of the horizontal rolls to scrape away instead of rolling or squeezing away the inside surfaces of the flanges; and not only this, but also the greater will be the friction of the horizontal rolls on the inside surfaces of the flanges, and, consequently, the greater the wear and tear on the rolls.

It is obvious that the application of the system described by H. Sack will result in a better beam, a stronger beam, a beam with a better quality of material in it, and diminished wear and tear of rolls, as compared with other systems which do not develop the flanges in an outwardly bent state

The author having been intimately associated with the late Mr. Hugo Sack whom he assisted in the development of his ideas has had the opportunity of making himself thoroughly conversant with the practical aspects of this particular process and he feels convinced that no other system at present known is so well adapted to produce commercially H beams of a good, sound quality as that which the late Mr Hugo Sack invented nearly twenty five years ago and upon which he brought his masterly mind to bear with such persistent energy and enthusiasm

The extensive trials carried on at the Rombach iron works have proved the soundness of the system and they have shown that the direction in which improvements can still be made lies chiefly in the adaptation of the plant for producing large quantities of material on a commercial basis with a minimum outlay in capital expenditure and working cost To this end the author has endeavored to apply the experience he has acquired and ventures to give the results of his efforts in the succeeding

From what has been stated in the foregoing it will be understood that in order to produce H beams free from fins there is a choice of two distinct systems First the mill may be so constructed that one set of universal rolls operates upon the whole of the section excepting where the unavoidable gaps occur between the rolls the positions of which gaps must be changed frequently or at every pass this being attainable with one set of universal rolls forming an unsymmetrical pass as regards the location of the gaps or with two sets of universal rolls each forming a symmetrical pass but each different as regards the location of the gaps—that is to say using a single reversing universal mill and tilting the bar half round between the passes or using two universal mills—which may be reversing or non reversing—and shifting the bar from one to the other between the passes Secondly the mill may be so constructed that one set of universal rolls operates upon the greater portion of the section and is adapted to reduce and elongate the bar as a whole while a second set of rolls operates only upon those portions of the bar which are not operated upon in the first set and are adapted to reduce the bar locally but not to elongate it or reduce it as a whole—that is to say using a primary reversing universal mill in tandem with a secondary reversing mill the two situated so close together that the bar is operated upon by both at the same time although on portions a short distance apart

It is with the second of these systems that the author wishes to deal, because the first is already sufficiently well known and because he believes that the second possesses greater possibilities of development in the direction of economy

H Grey uses a primary reversing universal mill with four rolls operating upon the web and the sides of the flanges of the bar reducing and elongating the bar as a whole but leaving the edges of the flanges untouched and in tandem therewith a second reversing mill having two rolls which guide the bar and operate upon the edges of the flanges only Thus in the tandem mill at every pass the bar is operated upon all over and the formation of fins is prevented

Retaining the system of H Sack in which the beam is developed with outwardly bent flanges the author suggests the employment of a primary reversing universal mill having its four rolls shaped to operate upon the web and sides and edges of the flanges with the gaps between them located somewhat short of the extreme edges of the flanges and sufficiently wide to prevent the extruded metal from cooling too quickly and in tandem therewith a secondary reversing universal mill with rolls shaped to guide the bar and roll down the surplus metal extruded between the gaps of the primary rolls—Fig 15

Any irregularities which might still be left at the edges of the flanges after the last pass in this mill could then be eliminated altogether by properly shaping the rolls so that the final pass required to straighten out the flanges in the separate set of rolls would roll down or fill up any irregularities as the case might be and give the system a final finish all over The tandem system of rolling has the advantage that the beam is reduced all over and extrusions of metal beyond the limits of the desired contour rolled down all in one pass so that the mill may work uninterruptedly backward and forward and no time is lost in tilting or shifting from one stand to another The cost of the equipment should be very slightly if anything more than that of a single mill with a suitable tilting gear; but even if the cost were considerably greater it would be more than justified by the increased output and by the saving of the extra wages which would be incurred in the more elaborate manipulation The plan of such a mill is shown in Fig 16

Where two stands are used and the bar shifted from one to the other an increased output might be looked for proportionate to the increase in the cost of the plant and wages provided that two bars could be rolled simultaneously and non reversing engines used but it is just a question whether the quantity of a given section required to be rolled at one time would justify the additional capital outlay in the plant required for such an arrangement having regard to the fact that the rolls in both stands could be adapted for only one size of beam at a time

Various Finishes for Zinc

Some Interesting Technological Suggestions

Of all the metals entrusted to the electro plater for metalic coating or coloring not one is so easy to handle as zinc whether it is to be nickel brass copper silver or gold plated or whether it is to be colored brown gray violet blue green yellow or purple Not only is the electroplating of zinc easier but it is much the quickest accomplished It is a fact however that one's whole attention is required for the work

In nickel plating zinc particular care must be taken to remove all grease If lime is employed for removing the grease it must be washed off as quickly as possible because the zinc articles are very readily attacked by the lime The best method of removing grease from zinc (Zn) is by boiling it in caustic soda (Na OH) keeping it constantly in motion however It is then brushed off in a watery decoction of Panama bark rinsed in cold water (H_2O) and transferred to the rapid nickeling bath More advantageous however is an ordinary citrate bath because with its use with a current of three to four volts the object can be heavily nickeled in five minutes without moving it about

In brass-plating zinc special care must be taken to scratch it well after a few minutes and not with a steel but with a circular brass wire brush The opinion of many tradesmen that the scratching of brass or copper is purposeless is entirely wrong. The more an object is scratched the heavier a deposit can be had The brass bath for zinc consists of

- 1 500 parts pure potash H_2CO_3
- 60 parts chloride of copper $CuCl_2$
- 105 parts chloride of zinc $ZnCl_2$
- 640 parts nitrate of ammonia NH_4
- 30 parts cyanide of potassium CN
- 10,000 parts distilled water H_2O

This bath is used at a temperature of 77 to 86 deg F and with a current of three volts

In copper-plating zinc, the same process is resorted to as in brass-plating, but the copper bath can be so made up that the scratching of the object may be omitted. It is composed as follows

- 15 parts neutral acetate of copper CuO
- 12 parts spirits of salammoniac, NH_3 (Spec grav 0.96)
- 35 parts crystallized soda, Na_2CO_3
- 15 parts pure sulphite of soda, Na_2SO_3
- 16 parts cyanide of potassium (99 per cent) CN
- 10,000 parts distilled water, H_2O.

If the articles to be copper-plated are of cast zinc it is better to use a copper bath with which scratching is [illegible]. Such a bath is made up as follows: [illegible] parts blue vitriol $CuSO_4$

- 1 500 parts seignette salt (potassio sodi tartrate) $C_4H_4O_6$
- 800 parts caustic soda NaOH
- 100 parts spirits of salammoniac NH_3
- 10 000 parts distilled water H_2O

If cast zinc articles are scratched any non-conducting casting residues that may be present will be eliminated and a much finer coating is obtained than without scratching

When silver plating zinc special attention must be bestowed on thorough amalgamation Every spot where the zinc has no coating of quick silver will after the scratching turn black in silver plating and the entire work will be useless The amalgamation or quickening bath is made up as follows

- 150 parts of cyanide of mercury Hg $(CN)_2$
- 150 parts cyanide of potassium CN (99 per cent)
- 10 000 parts distilled water H_2O

Having assured ourselves that the object is well cleaned it is then drawn quickly through the mercurial solution and rinsed off in clean water After having been passed through once more they are ready for the silver bath If the perfect removal of grease is doubtful then the quickening bath must be diluted with one third the volume of distilled water so that the zinc objects can be allowed to remain longer in the solution Care is however necessary for even the heaviest plates will crack in the quickening bath In silver-plating a very strong current is turned on at once but it is allowed to act for but a short time (one to one and a half minute) and the tension is reduced to one to two volts After five minutes the goods are transferred at once to the scratching bench and after washing another quickening is advisable The density of the silver bath should be about 10 to 15 deg Baumé.

The gilding of zinc calls for no very great experience A slight cleaning (pickling) suffices and the gold bath can be used as for other metals the gold being dissolved in boiling hydrochloric acid When the gold is all dissolved the chloride of gold ($AuCl_3$) is added to H_2O cyanide of potassium being at the same time added.

Zinc can also be readily colored without the employment of current, red for instance in the following composition

- 50 parts blue vitriol of copper $CuSO_4$
- 25 parts bi-carbonate of soda, Na_2CO_3
- 10 parts tartar, $C_4H_5O_6K$
- 10 parts sulphuric acid, H_2SO_4
- 1 000 parts distilled water, H_2O

The articles are immersed for a short time in the bath, which soon deposits a fairly heavy copper coating. Zinc as a component of brass, cannot be brass plated without current but is very easily gilded For silver plating it is likewise necessary to use the electric current

The patina on zinc is produced as follows

- 100 parts hypo sulphite of soda $HNaSO_4$
- 1 000 parts distilled water H_2O at 100 deg C
- 50 parts English sulphuric acid H_2SO_4 (stirring constantly)

In the decanted solution of about 60 deg to 70 deg C (140 deg to 158 deg F) of sulphite of soda Na_2SO_3 and sulphurous acid H_2SO_3 pickled pieces of sheet zinc are laid After one to three minutes they acquire a pale green very brilliant coating By frequent treatment the deposit is changed to the deepest gray color

Iridescent colors are obtained in the following solution

- 10 parts dry tartrate of copper Cu_2OH_2O
- 2 parts caustic soda NaOH
- 150 parts distilled water H_2O

According to the duration of the stay in this bath, we attain from a violet color to a very dark red

If a marbleized finish is desired pour on the sheet zinc while the coloring is still wet in some places hydrochloric acid and immediately after rinsing a five per cent solution of sulphate of copper in H O

To a previously mentioned solution of sulphurous acid add

- 15 parts chrome alum $Cr_2 3SO_4 + K_2SO_4 + 24H_2O$
- 1[?] parts hyposulphite of soda HNaSO

whereby a more brownish color is imparted to the plates

A bronze finish can also be produced on cast zinc but in this case a previous brass plating is necessary After this the dried objects are painted with a solution of

- 100 parts gold sulphur SbS_3
- 50 parts salammoniac, NH_3
- 10 parts hyposulphite of soda $HNaSO_4$
- 50 parts acetate of alumina Al_2O_3

Dried in a warm stove then again coated and after dying brushed with a soft brush By dipping in a ten per cent solution of cyanide of potassium (CN in H_2O) the coating becomes black.

To color the zinc directly black the arsenic bath composed as follows is used

- 1 000 parts arsenic, As.
- 100 parts cyanide of potassium CN 99 per cent
- 40 000 parts distilled water, H_2O

The articles change from green to blue, red brown, violet and slowly turn a deep black —Translated from *Die Edelmetall-Industrie* for the SCIENTIFIC AMERICAN SUPPLEMENT

A Remarkable American Forest Railway

The Profitable Industrial Road in Michoacan, Mexico

By A. Reiche

When the twin ribbons of steel blazed the way through the wild western lands the United States began to grow with rapidity. The railroads opened untold possibilities and then developed them. The same thing in a smaller degree is and has been true in other countries, notably Mexico.

It is said by enlightened visitors to the republic presided over by President Porfirio Diaz that Mexico has been standing still because the majority of its inhabitants are ignorant. It has been the American on the line of the Mexican National Railway to the hacienda San Joaquin Jaripeo. The province of Michoacan lies half way between Mexico City and the Pacific Ocean and is in the foothills of the southern range of the Sierra Nayarit Mountains.

The hills and mountains in this part of Mexico are covered with a dense forest of oak and pine which grow to a height and size not often reached in the United States, as may be seen in the accompanying engravings.

scale. The distance from Huingo to the [illegible] 24 kilometers (14.9 miles) and it was decided to build their mills at the hacienda, making the line from there to Huingo the main line, and [illegible] fairly heavy construction, while from the hacienda out through the forests branch or feeder lines were to be laid which would be of lighter construction, of narrow gage and therefore could be easily shifted and moved as desired.

After consultation with a well known Pittsburg com-

who has carried a spirit of enterprise into the country and rel[illegible] the backward and unprogressive land [illegible] to a progressive one which is now rapidly forging ahead.

Railroads have done their big share in Mexico's transformation and no small part must be given to [illegible] the narrow gage lines which [illegible] the density of the forest and unlock the doors of untold wealth that for years have been hidden because of [illegible] means of transportation. Over plains, through valleys and ravines, over mountains and through forests, the industrial railway has been [illegible] establishing a means of easy communication between vast and wealthy plantations and the marts of trade [illegible] the centers of densely inhabited Mexico along her seaboard.

One of the most profitable industrial railways through a Mexican forest is in service in the province of Michoacan and extends from Huingo, a station

On account of the rapid development of railways and mines in Mexico and the coal deposits not having been developed to any considerable extent, there is a large demand for lumber, railroad ties and wood for locomotive and furnace fuel uses. This demand is greatest in northern Mexico, and as the forests in Michoacan afford the nearest and best supply, it can be seen why great inducements were offered to the land owners to develop their timber property. This the owners of the hacienda San Joaquin Jaripeo, one of the largest estates in Mexico, did to some extent for several years, but as they were compelled to convey the timbers to the nearest railroad station, Huingo, by mule and by ox teams, very little progress was made, as they were not in a position to take large contracts and the cost of haulage grew prohibitive as soon as the distance became larger.

They finally determined to construct a railroad for their own use and to develop their land on a large

pany it was decided to construct the main line of a 48-inch gage or 1219.2 millimeters, while the branch lines were to be a 24-inch gage or 609.6 millimeters.

They accordingly placed an order with the above-named company for the complete equipment, consisting of rails, switches, locomotives and lumber cars.

From the survey it was found that the country sloped downward from the hacienda steeply for the whole distance, and that instead of having to plan the line to avoid grades against the loaded trains, it would be a question of making the grade small enough to permit locomotives of the ordinary type operating on it and at the same time have tractive power sufficient to haul back the empty cars. A line was finally laid out which averaged about five per cent down grade. This was accomplished partly by avoiding as much as possible all points which would cause heavy excavation or high fills and blasting of rock. While this policy made the line [illegible]

SKIRTING A HILLSIDE WHERE THE SKILL OF THE ENGINEER IS TAXED

SOME OF THE TIMBER

TRESTLE OVER A DEEP GORGE

A REMARKABLE AMERICAN FOREST RAILWAY

more degrees of curvature than would be regarded as standard practice in railroad construction yet it avoided the necessity of using an extensive plant for construction work, and what was more essential, the need of skilled laborers.

The only labor obtainable in the surrounding country were the peons who lived on the hacienda and as bids obtained for the construction work were enormously high on account of the remoteness of the place and the comparatively small job the owners decided to do the work themselves by using only their own plantation laborers This of course added to the length of the time the line was under construction, as the force at work varied at different seasons of the year according to the other demands on the laborers but resulted in a very cheap construction account, in spite of the fact that it was not possible to avoid some very deep cuts and the construction of numerous bridges and trestles as can be seen pictured in the illustrations.

The excavation work was done entirely with hand labor by pick and shovel with the aid of an equipment of the well known V-shaped double-side dump cars of one cubic yard capacity and of portable track which are built by the Koppel company This outfit was ideal for the purpose as the units were all light enough to be easily handled by a few men on any ground The cars of course were hauled by mules or oxen.

The abundance of fine timber supplied the material for the bridges and trestles, and trestling was done wherever possible, as it required less skilled work than bridge construction called for, and the units to be handled were smaller

Handling of rock was avoided as much as possible, as stated, and one of the illustrations shows a detour made to escape some boulders.

As soon as the main line was completed which took about two years the narrow gage lines radiating out from the hacienda were started and are being extended gradually as required

The equipment of the lines consists of platform cars (for which the iron parts were purchased the super structure being built by the owners) locomotives of 40 and 50 horse-power for the main line and lighter ones of 20 horse power for the 24 inch gage lines There are also some passenger cars and a private car for the use of the owners and their guests

It can readily be seen that the only work done by the locomotive on the downward trips is in controlling the speed of the train by its braking power

A party from the ranch often takes the private car and runs down to Huingo governing the car by brakes

With regard to the cost of the line no exact con struction expenses were kept but the total expenditure on the lines so far constructed including equipment has been from $600 000 to $700 000 Mexican or $300 000 to $350 000 gold

As soon as the main line was finished the project was placed on a paying basis almost at once as the owners were able to take large contracts for railway ties and fuel from the Mexican National at excellent prices

Although the extent of this road is not so very great and no great engineering works were involved in its construction yet it is interesting from the fact that it was built and brought to a satisfactory conclusion by unskilled labor and by supervision through wild and mountainous country It also shows the value of such narrow gage or industrial railways for cheaply developing the resources of a country which otherwise would be inaccessible for the use of mankind

To coat iron with a covering of lead which will be in absolute metallic contact states the Chemical Trades Journal is a difficult operation Valves and small fittings made of ir n well galvanized on the exterior may be hom geneously c vered with lead in the workshop by any mechanic The method consists in immersing the piece to be coated in water to which a few drops of sulpl uric acid have been added Then while in the acid water the piece is readily amal gamated in the usual way by squeezing mercury through close-woven cloth all over its surface and thoroughly rubbing it in The excess mercury is rubbed off and the piece carefully dried without heat, and then immersed in a bath of lead which should be well above its melting point so that it would not tend to solidify by introduction of the cold piece The casting may be withdrawn after about 20 seconds and will be found to be homogeneously covered with lead This i ethod requires the piece to be galvanized before applying the lead and the galvanizing must be in good condition otherwise the subsequent amalga mation will be imperfect On account of the mercury fumes given off it is not an operation one would wish to carry out day in and day out and on large pieces but the method is simple and of cours can be applied to any metal or alloy that can be amal gamated

Science and Engineering*

Sir J J Thomson's Comments on a Vital Subject

CONSPICUOUS among the qualities which have raised Sir J J Thomson to a foremost position among living physicists has been the success with which he has been able to imagine working models of the complicated electrical processes which he has investigated with so much originality and power He appears indeed to regard physical phenomena from the standpoint of the engineer and not from that of the philosophic mathematician whose equations are but pale reflections or images of substantial particles of matter in motion but merely a collection of recipes for acting or reacting on Nature This latter mental attitude at one time greatly favored in certain parts of the continent is no doubt logically inexpungable but it may be safely asserted to have been almost barren of results being conducive neither to the establishment of new facts nor to the origination of fertile speculations It is what may perhaps be termed Sir Joseph's Faradian methods of exposition which have rendered his annual course of lectures at the Royal Institution so peculiarly fascinating to those who while desirous of learning something as to the present drift of the unceasing advance in matters scientific have neither time nor opportunity to make a serious study of mathematical physics

In his presidential address to the Junior Institution of Engineers dealing with The Relation of Pure Science to Engineering Sir Joseph attributed his tendency to regard physical phenomena as reducible to aggregates of matter in motion to the fact that like the late Henry Rowland of Baltimore he commenced life with the intention of becoming an engineer and in his case studied to this end under Prof Osborne Reynolds one of the ablest and most original thinkers that has ever filled a professorial chair in engineering Circumstances led Sir Joseph subsequently to choose a fresh path in life and science has gained what engineering has lost It would seem however that he has never seen reasons to regret his earlier training for a profession in which it is all important to study actual phenomena and not merely the mathematical forms by which their interrelations can be more or less successfully expressed

In his address he claimed that the methods of the physicist and of the pioneer working in the engineering field are largely akin and indeed Mr Swinburne has expressed much the same view in one of his own presidential addresses The difference between the two lies mainly in the aim The physicist is in the fortunate position of being able to seek out the facts of Nature with no ulterior motive while the engineer's groupings in the well of truth are in the main to be quite frank a hunt for dividends The justification for his work must be found in the fact that in one way or another it must pay Where this necessity is removed as in government service stagnation seems inevitably to result A leading American authority has remarked that up to the taking over of the telegraphs by the government some thirty years ago the improvements made were almost wholly of British origin but since then they have been almost exclusively exotics although in able telegraphy, which remains in private hands we still retain our supremacy as fertile and original workers Similarly the many thousand miles of state railways in operation abroad have contributed practically nothing to the solution of problems in transportation

The luckier physicist who finds his sphere in the laboratory or in the study needs no commercial justification Shallow thinkers will doubtless hold that the aim of the physicist must accordingly from the standpoint of the moralist be ranked higher than that of the engineer but any attempt to institute an effective divorce between idealism and materialism is as futile as that to solve the famous problem as to the relative priority of the bird and the egg The existence of the one presupposes that of the other and while the world rightly honors those engaged in the pursuit of science for its own sake such a pursuit is rendered possible solely by the fact that the engineer and the business man are attending to the more immediate and pressing necessities of mankind He who invests in consols or municipal securities escapes indeed the thoughtless taunt of being a mere greedy hunter of dividends but is in truth a less useful member of society than if in the hope of a larger return he had aided in the development of say the telephone the steam turbine or the aeroplane

As was perhaps to be expected Sir Joseph proved himself a strong advocate of the works laboratory and research department and he remarked that the balance sheets of those firms whose laboratories were the most extensive did not suggest that they were ruining themselves in the cause of science It would seem, however that in many cases the laboratory is as much the result as the cause of large dividends It is, indeed impossible for a firm which returns its ordinary shareholders a mere 5 or 6 per cent in a good year and nothing at all in a bad one to embark on a large expenditure on pioneering work which is necessarily of a highly speculative character Such gambling risks can only be run by more prosperous undertakings and the struggling firm has perforce to content itself with business of a more humdrum character Fortunately we still have some highly prosperous engineering firms who are in a position to make ventures in experimental work to the extent of many tens of thousands per annum In mechanical engineering however the laboratory will always play a somewhat secondary part its utility being much less marked than it is in the case of chemical and metal lurgical establishments The Parsons steam turbine for example was raised from little more than a toy to its present pre-eminence with appliances in the way of laboratory equipment which would excite the derision of a Continental engineer One foreign firm noted for the lavishness of its expenditure on laboratory research is said to have expended nearly half a million sterling on the unsuccessful attempt to excel the Parsons machine calling to its assistance university professors demonstrators and graduates in engineering who were most liberally financed However in real pioneering the engineering laboratory probably counts for little Ability of the first order is not purchasable at will in the open market and the works laboratory is commonly staffed with less original men who are however often extremely useful in developing ideas from outside

Sir Joseph in his address raised a timely protest against the not uncommon but short-sighted contention that it is a wise plan to let other nations spend their money in developing new processes and to wait until the preliminary difficulties are overcome and success assured before taking them up Against such a policy there are many arguments Even as a matter of pure finance the practice is unsound The profits of successful pioneering are extremely large In the early day of the heavy electrical industry in this country dynamos costing some £30 to build readily sold for over £90 and the profits thus secured sufficed to build up an establishment which starting with a total of some four of five hands had become in three or four years the largest in the world engaged in that class of work and employed hundreds of work men Its prosperity was then checked and all possibility of further pioneering in the heavy electrical trades destroyed so far as this country was concerned by Mr Joseph Chamberlain's disastrous Act of 1882 The fallen scepter passed to America and to Germany where the enormous establishments of the A E G not only pay regularly a high dividend to their fortunate shareholders but the works themselves with all their elaborate plant and equipment stand on the books at but a nominal figure having been written off out of profits

The monetary returns attendant on successful pioneering constitute however only one of its advantages The process opens a career to men whose *forte* lies in their originality rather than in their organising ability or painstaking industry Moreover almost every firm that has tried it will we think admit that it is not possible to purchase experience over the counter along with working drawings Many for example have taken up the manufacture of large gas engines to Continental designs paying heavily for the privilege in the fond belief that they would thus at once be able to put the construction of such engines on a manufacturing basis In many cases however the transaction has resulted in serious loss and disappointment and it has been necessary to spend large sums in acquiring by trial and experiment that experience which they vainly imagined they had secured by the simple process of purchase

To no small degree this history is repeating itself in the case of Continental designs for steam turbines An instance could be quoted of two firms engaged in a very similar class of work both of whom decided to take up the manufacture of small steam turbines. The one purchased a Continental design, costly to build and but moderately efficient, and have not yet attained to commercial success in spite of much work The other firm entering the field later determined to build their own turbine *ab initio* and succeeded The very first built ran without a hitch from the start gave most excellent results in the matter of steam economy and actually cost less to construct than was paid in cash down for its Continental rival, which is, moreover, still subject to a royalty per horse-power turned out. It may be added that the firm bold enough to construct its own machine realised from the outset that the supposed necessity for employing technical students from Continental schools for such work is wholly imaginary and is likely, owing to their imperfect knowledge of the practical side of engineering, to lead to serious losses of time, money, and material. The thermodynamic aspect of the steam turbine is, indeed much less important than the mechanical, and a sufficient knowledge of the theory is not difficult to acquire

In concluding his address Sir Joseph insisted on the importance of a knowledge of mathematics to the engineer and it is a view with which we have much sympathy although it must be confessed that in mechanical and constructional engineering, as opposed to electrical opportunities for the useful employment of higher mathematics are few and far between Still the training is valuable although experience has shown that certain types of men are inclined to use mathematical formulæ as a substitute for serious thought The late Sir Benjamin Baker had he had time for it, could probably have derived profit from even a minute study of the mathematical theory of elasticity Smaller men however, find it difficult to resist the temptation to design structures so as to simplify them mathematically sacrificing to this end much more important considerations Indeed this tendency seems to have been at least partially responsible for the Quebec Bridge disaster as it was also for the collapse not long ago of a very large shipbuilding crane supplied by a leading Continental firm A well known American engineer again has declared the use of plate girders to be most unscientific since it is impossible to calculate with reasonable accuracy the stresses to which they are subjected Riveted trusses meet the same condemnation although experience with them as with plate girders has been most satisfactory

At Winnipeg last year Sir Joseph drew attention to the great difficulties attendant on the application of mathematics to physics and we believe that the difficulties are even greater in the case of mechanical engineering The partial differential equations which arise in the mathematical theory of elasticity are, in fact very much more complex than those of Laplace which we presume may be taken as the basis of mathematical physics It is morever even in solvable cases extremely difficult and indeed, often impossible to make the boundary conditions," necessarily assumed agree with actual practice To this may be added the fact that no adequate theory as to strength of statically indeterminate structures exists though the stresses can often be calculated with practical accuracy Thus in New South Wales there are now standing apparently satisfactorily a number of reservoir dams in which the stresses calculated by the mathematical theory of elasticity exceed the breaking strength of the material and we question whether an engineer well versed in this theory would have ventured to erect them They are, nevertheless highly economical of materal and prolonged experience of a somewhat similar type in the United States gives reason for believing that they are safe

In fact in all but the simplest class of structure or machine part the mechanical engineer has to rely upon physical rather than on strictly mathematical considerations He forms an image in his own mind as to the general character of the stress distribution and of the various ways in which failure may occur and provides for these by somewhat rough and-ready methods In the case of the Assouan Dam for instance while his Continental colleague was much concerned as to the necessity of keeping calculated stresses below a certain limit, the late Sir Benjamin Baker attributed less importance to such considerations, since the severest stresses to which the structure would be subjected would, he knew, arise from incalculable changes of temperature He paid special attention, accordingly to the stability rather than to the strength of the structure.

The foregoing comments are not intended to belittle the importance of mathematical knowledge, but merely to draw attention to the extreme difficulty of applying mathematical theories in one particular, but very important branch of engineering, and to draw attention to a certain danger, which experience has shown to exist, that a skilled mathematician may design a structure to suit his methods of computation rather than to carry its load in the most effective way. The mechanical engineer has, in practice, often to employ methods of reasoning akin to those of Faraday; and it is, perhaps, doubtful whether it will ever be possible for a Clerk Maxwell to throw them into strict mathematical form.

* *Engineering*

Trans-oceanic Aviation

An Analysis of Brucker's Project

THE recent long distance flights demonstrating the improvements that have been effected in the construction of aeroplanes both theoretically and mechanically, have revived says Engineering the interest in some ambitious schemes proposed to test the capacity and the outlook of aerial locomotion. Foremost among these is the plan to cross the Atlantic in an airship. Such a project had its origin in the fertile brain of an American journalist Mr. Joseph Brucker and his enthusiasm has so far affected others that a committee has been formed which on both technical and financial grounds is capable of starting this project on the road to fulfilment. The scheme has advanced to the point of placing contracts with German firms of recognized standing who are prepared to provide the necessary equipment which will include in addition to a dirigible balloon of large dimensions, a stout seaworthy boat to be attached to the airship and to be used in case of accident to the aerial apparatus. The plan involves therefore not only the carriage of a certain number of passengers across the Atlantic but also of a vessel in which the journey might have been made. While we commend the caution thus exhibited it is evident that trans oceanic flight handicapped in this manner will make little progress.

The balloon itself is necessarily a serious affair but far less capacious than a Zeppelin. It will be of elliptic form about 160 feet long and nearly 50 feet in diameter in the center. To obviate the difficulties arising from solar radiation the gas bag will be inclosed in an outer covering of some non heat-conducting material leaving an air space of 4 inches or 6 inches between this covering and the gas bag proper. At the same time a ballonet of peculiar construction which is still a matter for experiment will be provided. In this way it is assumed that the loss of gas will be reduced to a minimum and no untoward circumstances arise from the inevitable heating of the balloon covering. Immediately under the balloon there is to be a platform capable of accommodating a crew who will have to attend to the steering balancing gas control etc. and below this again in the place the car usually occupies will be a substantial boat 30 feet long and about 9 feet beam. In the hold of this boat will be carried a motor of some 40 horse-power capable of revolving the air propeller or if adverse circumstances supervene the screw of the boat when lowered into the water. This boat also carries a large tank of gasoline provisions kitchen galley etc.

Numerous ingenious devices have been introduced and that the scheme is practicable for a certain distance may possibly be admitted. But the step from covering a few hundred miles on land to one of some thousands over sea is a formidable one. It may not be too much to say that the risks increase with the square of the distance traversed. One would like to have more assurance on the question of navigation or the accurate determination of position. Ocean currents of a slow moving and well recognized type and of whose position the navigator is perfectly aware can work very disastrously on ships and it seems not impossible but that in the swifter and unknown aerial currents there may lurk a source of danger which has been very inadequately apprehended. One can imagine circumstances in which the compass would become useless and sextant observations more uncertain than on the unstable deck of a ship. But the dangers threatened from these sources are so obvious that we may be sure they have been considered and provided for by the members of the committee of which we have spoken.

The proper course for the airship to follow has been a matter of grave consideration. The principle that determines the laying of a submarine cable does not apply here. The shortest course naturally confined to high latitudes is not the most suitable. The one factor to be considered is the prevailing direction of the wind and this when known will decide both the most judicious course and the season of the year for the attempt. The air-current known as the trade wind which carried the frail bark of Columbus to a safe haven in the West Indian Isles will be selected to carry the first airship above the waves of the Atlantic Ocean. The trade winds secure a tolerably uniform current of air in a zone varying little from 20 deg north latitude. In the winter and spring months a velocity of from 14 to 16 miles an hour can be confidently anticipated and these are also the months that are most free from disturbing cyclones. Therefore the attempt will be made in the spring and the direction of the current from east to west decides that the aeronauts shall start from Europe and endeavor to reach America. Not only will the force and direction of this current prove of great assistance but in the zone in which it obtains there is small variation in the daily temperature. Since it is desirable to keep the gas at a constant temperature this fact is also in favor of the route etc. of the scheme. The greatest chance of success therefore points to a course which starting from Cadiz will pass by Madeira and Teneriffe and maintaining a generally W. S. W. direction will endeavor to make Porto Rico. Thence along the chain of islands leading to Havana this course is easy. On leaving Cuba New Orleans will be the goal and finally across the States to New York. The whole passage involves a journey of more than 7 000 miles divided as follows:

	Miles
Cadiz to Teneriffe	807
Teneriffe to Porto Rico	3 219
Porto Rico to Havana	1 124
Havana to New Orleans	674
New Orleans to New York	1 382

It is estimated that the journey across the ocean can be completed in five or six days but the airship will be provided with gasoline and equipment for a much longer period.

Supposing the experiment is carried to a successful issue it will be asked What does it prove? What new scientific fact has been gained? What prospects does it open up for improved locomotion or more economical modes of transit? We must confess that however dazzlingly the project may appeal to the imagination however convincingly it displays the power of science and ingenuity it will remain we believe a barren result. The promoters must naturally take a more hopeful view. It is for them to put forward some tempting by-products as an inducement or as an excuse for the expenditure and the risk. They urge that meteorology will be provided with more exact knowledge of the behavior of the trade winds and of the motion of the upper atmosphere while aeronautical problems will be studied on a scale which will remove the hindrances by which advance is now beset and introduce processes that will revolutionize the ordinary methods of travel. Advocates of aviation foresee the construction of airships that will have a velocity which combined with that of the trade wind will transport the hardy aeronaut to America in the short space of fifty hours. We find it difficult to share these roseate views at least as the result of a single experiment. What form aerial craft may be destined to assume in the future cannot be predicted but as far as can be seen at present high velocities are limited to the heavier-than-air machines. By constantly increasing the velocity the area of the supporting surface may be as continuously reduced and this rule may point to the adoption of a form of helicopter as the racing machine of the future. The possibilities of the dirigible balloon seem limited to being the burden-bearing machine of the future capable of carrying considerable tonnage at a low speed. In this capacity a very useful career lies before it.

Fog Scales

IN the United States observers of the Weather Bureau designate as a dense fog one that obscures objects at a distance of 1 000 feet. If objects are not obscured at that distance the fog is described as light.

Is it desirable and feasible to describe the gradations of fog more minutely? English meteorologists have answered this question in the affirmative. The London Fog Inquiry of 1901 1902 conducted by the British Meteorological Office gave precision to many of the ideas of meteorologists concerning fog and one of the results of that inquiry was the adoption by the Meteorological Office and the Admiralty of a fog scale of five steps as follows:

	On Land	On Sea	On River
Slight fog or mist.	1 Objects indistinct but traffic by rail or road unimpeded	Horizon invisible but lights and landmarks visible at working distance	Objects indistinct but navigation unimpeded
Moderate fog	2 Traffic by rail requires additional caution 3 Traffic by rail or road impeded	Lights passing vessels and landmarks generally indistinct under a mile. Fog signals are sounded	Navigation impeded additional caution required
Thick fog	4 Traffic by rail or road impeded 5 Traffic by rail or road totally disorganized	Ships lights and vessels in visible at ¼ mile or less	Navigation suspended

For the determination of fog densities several forms of fog gage have been proposed though none of them have come into practical use. One suggested many years ago by G. J. Symons consisted of a white wooden screen, placed at a distance of 20 feet from the observer, on which were painted five black strips of different widths, the visibility of each strip corresponding to one of the five degrees of the fog scale. At night this was replaced by a lantern in front of which were to be placed five thicknesses of colored glass; these were to be successively removed until the light became visible at a distance of 20 feet. A more elaborate form of apparatus proposed by J. W. Lovibond in 1907 was based on the power of selective absorption resident in suitably colored glass and measured the brightness of a fog on a scale of thirty two tintometrical light units.

During the past year the Meteorological Office has been making experiments to determine more precisely the distance of visibility at sea by day and night corresponding to the five degrees of the official fog scale. The figures of the scale are based upon the interference of the fog with traffic and it is desirable to form some definite idea as to how far off a vessel or light is visible first when a fog-horn is sounded by navigators as a matter of ordinary precaution and secondly when extreme caution is judged to be necessary. The matter has been taken up with the Elder Brethren of Trinity House and arrangements have been made for observers at six lightships to note the state of atmospheric obscurity according to the numerical scale as judged by the requirements of traffic and at the same time to note the distance of known land and sea marks which are visible or invisible. The returns from the lightships are now being examined in the Meteorological Office and will form the subject of a special report.

Capt. R. E. Peary, famous for his expeditions in Arctic regions culminating in his discovery of the North Pole has deposited in the United States National Museum the series of sixteen gold and two silver medals that have been awarded to him. They include especially the great gold medal of the National Geographic Society of Washington presented to him for his discovery of the North Pole and the great gold medal of the Royal Geographical Society of London designed by Mrs. Scott wife of the leader of the British South Polar Expeditions and presented to Capt. Peary for Arctic Exploration 1886 1909. Also the following gold medals from American societies: The Cullum medal (first award 1892) and the C. P. Daly medal of the American Geographical Society of New York (first award 1902) the Hubbard medal of the National Geographic Society (first award 1906) the Elisha Kent Kane (1902) and the special medal (1909) of the Philadelphia Geographical Society and the Helen Culver medal of the Chicago Geographical Society (1910). The foreign medals received by him include the following all of which are of gold except the two specially indicated as of silver: Royal Scottish Geographical Society (1897) silver Royal Geographical Society of London (1898) Nachtigal medal of the Imperial German Geographical Society Hauer medal of the Imperial Austrian Geographical Society (silver) the Paris Geographical Society David Livingstone medal of the Royal Scottish Geographical Society (1903) King Humbert medal of the Royal Italian Geographical Society (1909) Royal Geographical Society of Belgium (1909) Royal Geographical Society of Antwerp (1910) and the Royal Hungarian Geographical Society (1910). Capt. Peary has also deposited in the National Museum the flag of his college fraternity which was presented to him by his brothers of the Delta Kappa Epsilon and the Peace Flag which was presented to him by the ladies of the Society of the Daughters of the American Revolution. Both of these flags he carried to the North Pole.

European Transformer Towers

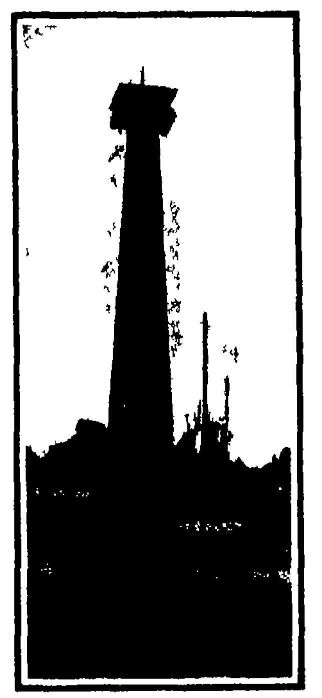
A New Type of Small-Sized Station

By the Berlin Correspondent of the Scientific American

A very suitable type of small-sized transformer station has been developed by the Oerlikon Machine Works which shows a number of advantages over masonry stations Apart from a considerable reduction in first cost and the possibility of readily shifting the station whenever required they are in fact fitted up completely at the factory and after being installed on their foundation are got into working order merely by connecting up the primary and secondary conductors as well as the transformer Owing to their pleasant exterior and small space requirements these stations can be installed anywhere in the midst of other buildings the more so as their painting can be adapted to the surroundings

Transformer towers are generally made of frame work comprising at the base a cabin for receiving the transformer and apparatus being designed as lattice poles they are of a very pleasant appearance and afford a point of support both safe and simple for use in connecting up any kind of conductor

TRANSFORMER TOWER HIGH TENSION SIDE



GENERAL VIEW OF TRANSFORMER TOWER

TRANSFORMER TOWER. LOW TENSION SIDE

The cabin is so designed as to afford ample space for a straightforward arrangement of all the apparatus and conductors It is generally fitted with two operating doors for the purpose of controlling the high and low tension ends respectively but can be as well made accessible from all four sides The most up-to-date apparatus have been provided for the protection and superintendence of the transformer

A galvanized sheet-iron tube 30 to 60 centimeters (11 81 to 23 62 inches) in diameter is used for introducing the primary conductors into the cabin. At each of its ends a cast iron spider is fitted in its interior and it carries the tightening device for three or six bare copper wires. The sheet iron tube below the upper roof of the tower rises to a height sufficient to prevent any rain from penetrating into its interior and accordingly into the cabin The secondary conductors (14 wires as a maximum) are taken out of the cabin by porcelain pipes protected against rain by a special roof which at the outside of the sheet iron tube are likewise arranged in the form of bare conductors.

The admission of fresh air is effected through apertures in the foundation a lively ventilation of the transformer being insured by the violent draught in the admission tube These apertures are arranged in the top part of the foundation, immediately below the iron foot of the tower Another arrangement which though somewhat more expensive is considerably better excluding as it does the entering of splash into the interior of the cabin, comprises an aperture closed with a perforated plate on one side of the foundation and through which a supply of fresh air below the transformer is allowed to penetrate directly into the cabin.

Any water oozing out in cold weather inside the sheet-iron tube is allowed to escape through an aperture in its lower end.

The transformer towers above described are designed in three sizes, the space available for the transformer having the following dimensions

Size	Length in meters.	Height in meters.	Width in meters.
A	1.0 (3.28 feet)	1.5 (4.92 feet)	0.7 (2.30 feet)
B	1.2 (3.94 feet)	1.5 (4.92 feet)	0.9 (2.95 feet)
C	1.3 (4.26 feet)	1.5 (4.92 feet)	1.0 (3.28 feet)

The largest size suffices for the installation of a transformer of fairly large dimensions, unless it be preferred to put up two small-size transformer towers, the secondary bus bar being provided with switches for use in allowing the transformers to work separately or in parallel.

In connection with another type of transformer tower, the whole iron structure is coated with 'Eternite plates fixed in position by zinc or copper sheets.

Electric Locomotives for Lotschberg Railroad

Two electric locomotives are now being built for the Bernese Alps railroad of Switzerland which crosses the mountains by the Lötschberg tunnel and makes connection between the northern Swiss railroads and the Simplon line Of the new railroad line there is already built a section at the commencement from Spiez to Frutigen The locomotives will be run upon this section and it is now being fitted with the trolley wire for this purpose The company will thus obtain the necessary data for building the standard locomotives which are needed Owing to the heavy gradients adhesion is a prominent factor while speed is of less consequence The Swiss Oerlikon firm is building a 2 000 horse power locomotive It works on single-phase current at 15 000 volts taken by trolley There are used two bogies each carrying one motor and three driving axles All the wheels are used for adhesion The 1 000-horse-power motor of each truck drives a countershaft by 1 3 25 ratio gearing Crank and bar drive is used to couple to the wheels All the wheels of one side are connected together in turn by crank and bar drive. A single motor thus drives the three wheels The same drive is used for each truck The total weight of the locomotive is 9? tons of which the electrical outfit represents 46 tons The wheels have a uniform diameter of 1 35 meters (4 45 feet) As to the mechanical part of the locomotive it is built by the Swiss Locomotive Works The second locomotive is built by the Allgemeine Electric Company of Berlin and the Krauss manufacturing firm An entirely different construction is used Two separate half locomotives each mounted on a three-wheeled truck are coupled together The truck in each case has two driving wheels on a side and one pony wheel When coupled the entire locomotive presents four driving wheels at the middle and a pony wheel at each end Weighing in all 102 tons is uses 75 tons for adhesion on the four axles The large wheel diameter is 1 27 meters (4 17 feet) and the small wheel 0 85 meter (2 79 feet) On each truck is an 800-horse-power single-phase motor of the German Winter-Eichberg type making 1 600 horse-power in all which is somewhat less than for the preceding type A reduction gearing to countershaft and crank drive thence to the wheels somewhat analogous to the above, is employed here The two wheels are coupled by a driving bar The present locomotives have about the same capacity as the Simplon locomotives which are built for 1 700 horse-power However there are radical differences in the design

Our Myriad Government Publications

Of 1 982 department publications issued, 25,160 469 copies were printed an increase of 46 2/3 per cent in the number of publications and 41 per cent in the number of copies The Superintendent of Documents sold 147,327 copies of the department s publications. The number of copies sold has increased 205 per cent within five years Of the Farmers Bulletin on 'Economical Use of Meat in the Home 47,148 copies were sold, although 900 000 were distributed free Forty-five new Farmers Bulletins were issued, with a total of 2,915,000 copies, reprints of older numbers aggregated 6,247,500 copies The expenditure for printing and binding was $441,249 94

A Novel System of Cleaning Water Mains

In a system of cleaning water mains invented by Mr R A. Adamson the engineer at the Rivington Works an opening of 9 feet is made in the main to be cleaned and a bracket is fixed on each end of the opening These brackets carry two rails and a screw of coarse pitch A gasoline engine is then lowered into the hole so that the wheels on the frame rest on the rails, while the screw passes through the center of the machine The shaft of the engine is then central with the main The frame of the machine is fitted with a hand wheel, by turning which the machine is propelled along the rails in either direction by means of the screw A specially constructed knife formed of a central bar carrying four cutters is used for the scraping, and is attached to the shaft of the machine. The engine having been started up, the driver turns the hand wheel in the desired direction of travel, the result being that the revolving knife is gradually fed into the pipe after the manner of a boring machine. The apparatus is such that in long lengths it is possible to clean 200 yards in each direction from the hole, or 400 yards in all The speed of cleaning is about 50 yards an hour or in ordinary practice an average of about 300 yards a day The appliance has been seen in actual operation at Huyton by a number of water engineers, while the members of the Liverpool Corporation Water Committee are so impressed with its labor-saving properties that they have decided to adopt it, and a machine has been ordered.

Apotheosis and the Worship of Ancestors

Eagle, Peacock, and Serpent and their Significance in Roman Times

By P F Mottelay

ONE of the prominent members of the French Academy of Sciences recently called attention to the recent discovery of funeral monuments of the early Roman period bearing novel designs of the eagle Jupiter's bird, which had taken the place of the Egyptian hawk and was made to play such a very conspicuous part in the Apotheosis (*Consecratio*) of Roman emperors

Very curious and singularly interesting are the comparatively little-known details of the origin and progress of the rite of deification or consecration which at one time obtained so extensively for the Cæsars

Apotheosis is the natural outcome of the progressive worship of ancestors The more the latter had distinguished themselves in private or in public life, the greater of course was the reverence paid them To rulers of men who are ever prominently majestically before the world will always deservedly attach that amount of admiration which their exalted position and their attractive surroundings necessarily command and the greater the popularity they achieve through personal valorous deeds or by means of victories obtained either on field or otherwise for the benefit and aggrandizement of their states as well as for acts benefiting their fellow men the greater naturally will be the honors and admiration accorded them by their immediate followers their family and their descendants

The founder for instance at his death became as others the common ancestor for all ensuing genera

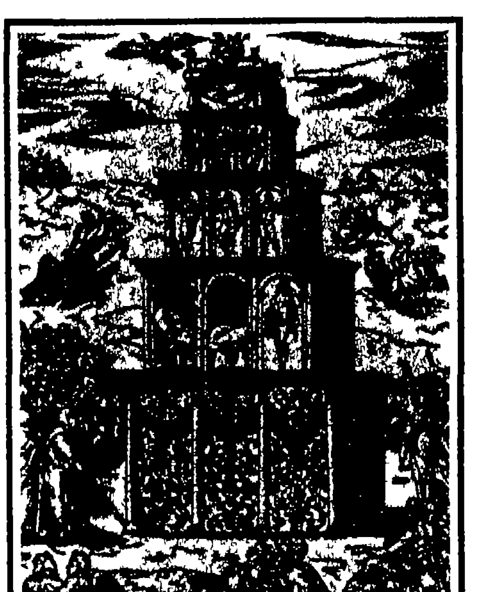


FIG 1—STRUCTURE BUILT FOR THE RITE OF APOTHEOSIS

tions and for the city he was what the earliest ancestor had been for the family His memory was easily perpetuated and later on in accordance with the customs prevailing yearly feasts were regularly held over his tomb and even sacrifices were made in his memory His fame grew at great pace and the increased honors attaching thereto which were gradually paid him extended afar so that beyond his original home and beyond his actual burial place as is pretty much everywhere the custom even at the present day honorary tombs and monuments were in due time erected to his memory As years progressed the story of the founder's deeds was amplified around it was weaved a more or less marvelous legend, while the poets and the writers consecrated it in records that were after awhile embellished and heightened to such an extent that the human original himself actually disappeared and he had become transformed into a being worthy of worship a god Thus it was Athens came to deify her two founders Cecrops the first king of Attica and Theseus the great hero of Attic legend Thus also Romulus founder and king of Rome, was proclaimed a god by the Senate as is well known, under the name of Quirinus

In Egypt where the ruling king was held as a god and was rendered anew all the honors bestowed upon his predecessors, the soul of the dead was first represented leaving the earth in the shape of a bird, then the bird was shown as carrying the soul itself. This idea of the soul-bird is borrowed from the stellar mythology teaching us that the sun is creator of souls by the sun is the soul created in human bodies and by the sun also is it recalled to heaven In Syria, the sun-god was himself represented borne upon the wings of an eagle It was at Hieropolis (Hierapolis) a city of Syria Cyrrhestica, that the goddess Atargatis had one of her most famous temples Atargatis was called by the Greeks Derceto and was worshiped

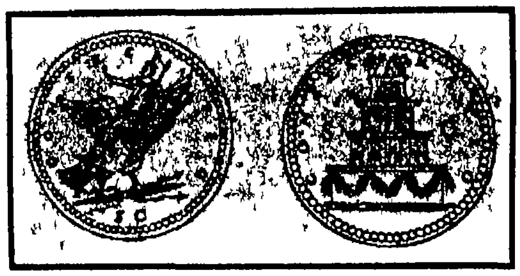

FIG 1—BRONZE MEDAL OF ANTONINUS PIUS FIG 2—REVERSE OF BRONZE MEDAL OF SEVERUS

under different names throughout pretty much the whole of Western Asia where are found many funeral monuments bearing an eagle the latter with outspread wings flying upward carrying a wreath in its beak or claws The wreath by the way denoted the victory of the soul over the evil one and it was said that the gods turned aside from those appearing before them without wreaths This silent form of deification at first prevailed everywhere but later on when the body of an illustrious dead was burned upon an altar an eagle was dispatched supposedly bearing heavenward the soul of the deceased This had been described by many authors but by none

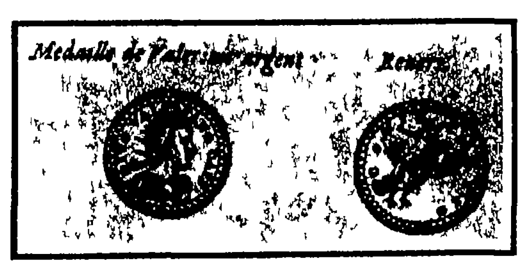

FIG 4—OBVERSE AND REVERSE OF SILVER COIN OF VALERIUS

more satisfactorily than by Herodian and Dion Cassius Their account of the customary ceremonies we think worth reproducing

There is placed in the palace vestibule upon a bed made of ivory and covered with a cloth of gold a waxen image of the dead representing him as still suffering and over whom guard is to be maintained for seven days At intervals during that period Roman Senators stand in black robes to the left of the image, while to the right and in white robes stand the ladies of the court and others holding high rank The doctors are daily in attendance and go through the form of recording the progressive decline in health of their patient until his death is finally announced When that is done the most distin

FIG 6—REVERSE OF BRONZE MEDAL OF FAUSTINA FIG 5—REVERSE OF MEDAL OF MARINIANA

guished dignitaries of the empire the senators and others carrying the couch bearing the real body likewise the bed holding the waxen image to the Campus Martius and place them upon one of the tiers of a high pyramidal structure which has been erected there covered with rich gold tapestries and ornamented by statues of ivory and by fine paintings and which has been filled with aromatic and other similar substances, with much incense and perfumes, as well as with offerings of all kinds This being concluded the court dignitaries and the military ride three times around the structure (*Decursio*) accompanied by chariots whose drivers wear flying purple robes and hold waving banners whereon are recorded the great deeds of happy rulers Then the reigning monarch fires the structure from the very top of which is allowed to escape an eagle mounting through flame and smoke into the sky for the purpose of carrying it is believed the soul of the dead from earth to heaven in order that the deceased may thereafter be worshipped with the other gods

It was in Rome that the apotheosis took its most regular form The first, after Romulus, upon whom apotheosis was officially conferred was Caius Julius Cæsar (100 44 B C) and after the victory of the triumvirs the senate bestowed upon him the name of *Divus Julius* the word *divus* having been employed in the same manner as *deus* The fact that during the brilliant ceremonies of his apotheosis a comet appeared was taken as a sign and to Augustus was proof conclusive that the soul of Cæsar had already been welcomed by the immortals C T Octavius Augustus (63 B C 14 A D) was the next to receive apotheosis and the ceremonies were the same as described by Herodian The fire it is said lasted five full days and into it the soldiers cast the arms borne by them during the ceremony as well as the medals and other rewards that Augustus had conferred upon them while the women cast in their jewelry and other ornaments and many of their vestments *Divus Augustus* was the name afterward given When apothe

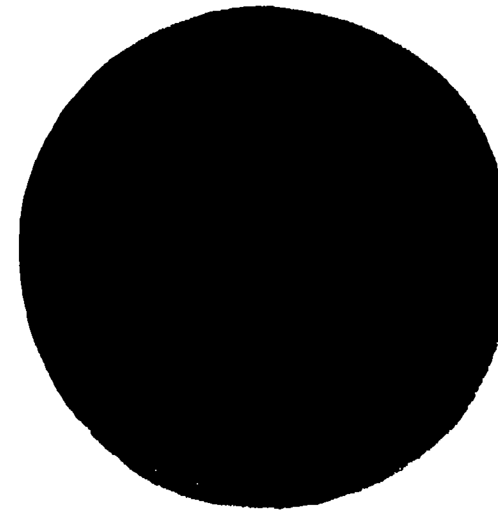

FIG 7—SUPERB BRONZE DISK FROM BRUSSELS MUSEUM SHOWING BAAL THE SUN GOD

osis was accorded to the emperor Antoninus Pius successor to Hadrian (86 161 A D) and to Faustina his wife (104 141 A D) two eagles were sent from the funeral pyre For the Roman emperor Publius Helvius Pertinax the Galba of his time successor of Commodus unusually fine ceremonies were observed His statue made of solid gold was carried upon a chariot drawn by elephants and the very high structure upon which the body was consumed was constructed of the finest woods and bore very many large ornaments of gold and of ivory This latter substance was by the way always used by the Romans for decorating the temples of the gods for the construction of thrones and for the ornamentation of the highest insignia

The English poet Dryden thus refers to the rite of apotheosis in the opening lines of Heroic Stanzas on the Death of the Lord Protector Oliver Cromwell (English Poets London 1810 vol viii p 498)

And now tis time for their officious haste
Who would before have borne him to the sky
Like eager Romans ere all rites were past
Did let too soon the sacred eagle fly

Incidentally it may be mentioned that the Greeks and the Hindus more particularly burned the bodies of their dead Among the Greeks it was the custom to burn the body after having bathed it in expensive oils and clothed it in most attractive vestments When the body was consumed the fire remnants were extinguished with wine then the ashes were sprinkled over with oils and with more wine after which the dishes were collected and placed in urns or other

receptacles The Hindus held fire as one of their gods (*Rig Veda* 11 1 7) under the name of *Agni* which carried the soul to the home of the blessed Like some of the other eastern people the Persians on the other hand did not burn their dead nor did they decorate the bodies with ornaments of gold that metal being of the color of the fire which they worshipped When a king died all the people of Asia were commanded to extinguish the sacred fire in their temples not to be relighted till after the funeral ceremonies The royal Persian tombs it may be added were always practically under guard that of Darius having thus been looked after for a period of seven years according to Ctesias (Herodotus vi 227)

In the accompanying illustrations taken from the excessively rare old work (C Guichard *Funérailles* Lyon 1581) found in the Sainte Geneviève library in Paris is seen at Fig 1 one of the forms of structure erected for the rite of apotheosis It shows the dead body of the king on the second tier the procession of chariots around the structure and *the eagle taking its flight In Fig 2 is represented* a different mode of structure upon the reverse of a bronze medal of Severus The other figures represent coins or medals of various rules showing the different forms in which the body was supposed to be taken heavenward Fig 3 is the reverse of a bronze medal of Antoninus Pius where the eagle is seen grasping thunderbolts Fig 4 gives the obverse and the reverse of a silver coin of Valerius Fig 5 is the reverse of a medal of Mariniana and Fig 6 the reverse of a bronze medal of Faustina In lieu of the design of an eagle the last two bear that of a peacock the favorite birds of Juno or Hera employed only when the apotheosis was that of an empress Upon the sides of a funeral altar in the Vatican can be seen the figures of G Pomponius Edaémon and of his wife Componia Helpis carried to heaven respectively *by an eagle and by a peacock*

In later days several emperors had medals struck showing the body taken by the griffin of Apollo (god of light god of the sun son of Jupiter and of Latona) and holding some attribute of the gods—the scepter thunderbolts or the *Fasta pura* The head of the emperor was sometimes made to bear a crown or it was surmounted by the nimbus and the body occasionally rested upon a throne or solar quadriga the latter being by the way admirably shown upon many of the coins and medals struck for the apotheosis of the much-esteemed emperor Flavius Valerius Constance Chlore father of Constantine

The eagle was ever a royal bird always employed as a symbol of force and of power It might be added that throughout heraldry it ranks as one of the most noble bearings in coat-armor

By the Persians, the eagle was placed upon spears as standards in the great battle of Cunaxa Babylonia B C 401 and it is said that the Romans adopted it for their legions during the second consulate of Marius their greatest general The first eagles were made of wood wreaths were soon added then these eagles were replaced by others made of silver with the bird resting upon golden thunderbolts up to the period of the Cæsars when the last-named gave way in turn to eagles made entirely of gold and deservedly *so for as Tacitus said (Ann II 17) the eagles* were by all considered the gods of the legions

Charlemagne introduced the eagle to denote that he held government over both the Romans and the Germans as shown upon the fine monument erected to him in the cathedral of Aix la-Chapelle As a sovereign emblem the eagle held its own throughout the fifteenth century and prominently because the emblem of the Holy Roman Empire The Napoleons also adopted it placing it upon the flagstaffs first between the years 1804 1814 afterward between 1852 and 1870 in accordance with a design of Isabey borrowed from the eagles to be seen upon the tombs of the Viscontis Some of these are in the Milan Cathedral which latter it may be added was begun in 1386 with brick cased in marble taken from quarries which the Viscontis gave in perpetuity

The eagle be it said is the fourth attribute of Christ denoting especially his divinity and his glorious ascension

In addition to the eagle upon funeral monuments we again find the griffin (part lion part eagle) as well as the serpent An unusually fine and very large Greco-Roman sarcophagus, brought to France in 11.., from Salonica, representing an episode of the war between the Greeks and the Amazons, is in the Gallery Denon of the Louvre Museum, and on it can be seen thick wreaths held by an eagle and two griffins. A serpent with an eagle s head is found carved on one of the tombs of the Porta Capena, and is reproduced in Tavola XXIX. of the attractive work published thereon by C L Ghassi. In the collection of antiquities belonging to the Bibliotheque Nationale Paris, are many notable cameos representing the apotheosis similar to those that are in the Vienna Museum and one of these shows an emperor carried to heaven by an eagle where he is about to be crowned anew with a wreath by an angel A fine sardonyx in Vienna is said to represent the apotheosis of Augustus, which is likewise represented in an attractive *basso-rilievo* in the chantry of the St. Vital Church in Ravenna Still more interesting is the bronze disk in the Brussels Museum (Fig 7) showing a serpent holding its tail and thus encircling the head of Jupiter, or more properly the head of Baal the sun-god of the Syrians Phœnicians, and heathen Hebrews, supported by a spread eagle whose wings appear as a luminous radiation

The serpent, when found upon funeral monuments is the symbol of renovation resurrection palingenesis He was made to represent those who had been deified From the highest antiquity he was classed among divine beings he was considered the guardian of sanctuaries In Egyptian mythology he is likened unto the sun i e life Among the Hebrews, the same word Héva signifies life as well as serpent. Among the Greeks the serpent biting its tail is the symbol of eternity for the serpent represents life and the circle thus formed is without end

It may be added that a very attractive emblem of eternity appears on many of the ancient monuments and upon medals or coins of Vespasian Titus, and others in the form of a woman holding in her right hand a head surrounded by rays to represent the sun and in her left hand a head bearing a crescent, to represent the moon such union of the two orbs of day and of night denoting the permanency of all time

Weighing the Earth, Sun, and Planets

The Mighty Scales of Mathematics

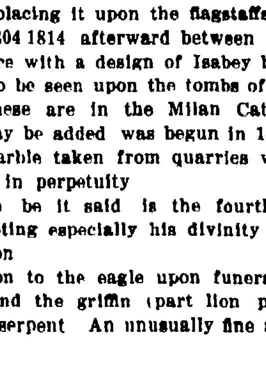
STRICTLY speaking says a writer in Kosmos the weight of an object is the force with which it is attracted by the earth This force is inversely proportional to the square of the distance from the earth s center Hence the weight of an object, as defined above and as measured with a spring balance is less at the equator than at high latitude and less on a mountain top than at the sea level The force of gravitation is proportional to the acceleration or rate of change in velocity of a body falling freely in a vacuum and the varying weight of an object as defined above is the product of its mass by the gravitational acceleration at the place of observation In the latitude of central Europe and the northern United States the velocity of fall *in vacuo* increases by about 32 feet, or 975 centimeters per second in each second of falling Hence the approximate numerical value of the gravitational acceleration (commonly denoted by the symbol g) is 32 in the English and 975 in the metric system

When an object is weighed on an ordinary balance with a set of standard weights however the result does not differ at different places because the object and the counterbalancing weights are equally affected by any variation in the force of gravity The operation is in fact a measurement of the mass of the object in terms of standard masses and this is what is commonly meant by weighing an object

Although we cannot put the earth in a scale pan we can weigh it with the aid of a balance

Prof Richarz filled a vault in the fortress of Spandan with 100 tons of lead and placed above the vault a balance from the pans of which two additional pans were suspended beneath the mass of lead by means of wires passing through vertical shafts which traversed the mass He found that two one-kilogramme weights which balanced when placed in the upper pans or in the lower pans did not balance when one was placed in an upper and the other in a lower pan although the additional weight required to restore the equilibrium was only about one milligramme The discrepancy was due to the attraction exerted by the mass of lead which pulled one of the kilogramme weights downward and the other upward From this experiment Richarz deduced the value of the gravitation constant, which expresses the force of attraction between two unit masses at unit distance from each other An idea of the magnitude of this force can be gained from the statement that the attraction between two masses each of one ton separated by a distance of one meter is nearly equal to the *weight* of 7 milligrammes The value of the gravitation constant in the C G S system in which lengths are expressed in centimeters masses in grammes and time in seconds is $6\ 7 \times 10^{-8}$

The attraction between two bodies varies directly as



WEIGHING THE EARTH WITH A BALANCE

the product of their masses and inversely as the square of the distance between them Hence the attraction between the earth and any object on its surface is $\dfrac{kMm}{\gamma^2}$ where k is the gravitation constant, M the mass of the earth m the mass of the body and γ the length of the earth s radius This attraction is equal to the weight of the object or mg where g is the gravitational acceleration Hence $\dfrac{kMm}{\gamma^2} = mg$, and therefore $M = \dfrac{g\gamma^2}{k}$

Substituting for g and k the values already given, and for γ the length of the earth's radius in centimeters, we find the mass of the earth, M, equal to 68×10^{26} grammes, or 68×10^{20} metric tons.

The volume of the earth calculated from its known dimensions is 12×10^{20} cubic meters Hence the density of the earth is about 5½ times that of water as a metric ton is the mass of a cubic meter of water

The mass of the sun is deduced from the attraction which it exerts upon the earth This attraction may also be expressed by the formula $\dfrac{kMm}{\gamma^2}$ but M now denotes the mass of the sun m the mass of the earth and γ the distance between the sun and the earth This attraction however is the centripetal force which holds the earth in its orbit and which is expressed by the formula $\dfrac{mv^2}{\gamma}$ in which v denotes the linear velocity of the earth in its orbit Hence $\dfrac{kMm}{\gamma^2} = \dfrac{mv^2}{\gamma}$ and therefore $M = \dfrac{v^2\gamma}{k}$ Substituting the values of v γ and k we find $M = 2 \times 10^{33}$ grammes or 2×10^{27} metric tons

The mass of the sun as thus determined is 325 000 times that of the earth The sun s diameter is more than 100 times and its volume is nearly 1,250,000 times, that of the earth Hence the sun is about four *times* less dense than the earth or not very much denser than water

The mass of any planet which has a satellite can be deduced from the distance and orbital velocity of the satellite as the mass of the sun is deduced from the distance and velocity of the earth The mass of a planet which has no satellite is obtained, less simply from the perturbations which it causes in the motions of other planets If the earth s mass is taken as unity, the masses of the other planets are Mercury 1/16 Venus ¾, Mars 1/9, Jupiter 300, Saturn 90 Uranus 13, and Neptune 16 The earth is denser than any other planet except Mercury The density of Saturn is less than that of water

The masses of the fixed stars can only be guessed from their relative brightness and distance and from the periods of rotation of some lunary systems, such as that of Algol in the constellation Perseus.

Exact measurements are out of the question.

INDEX OF INVENTIONS

For which Letters Patent of the United States were issued for the Week Ending January 17, 1911,

AND EACH BEARING THAT DATE

[See note at end of list about copies of these patents.]

Acid, production of compounds of persulfuric, G. Teichner 981,900
Acoustic diaphragms, making W. W. Young 982 027
Adding machine for cash registers, etc. F. L. Fuller 981,683
Addressing plate, U. G. Lee 982 076
Agricultural implement seat mounting H. T. Ingram 982 063
Agricultural system, electrical, C. S. Doney 982 175
Air and its separation into its constituents, liquefaction of G. Claude 918 748
Air brake coupling automatic, T. E. Jennings 982,004
Airship J. M. Keller 981 655
Airship E. L. Madden 981 778
Alarm. See Temperature alarm.
Alarm system electrical thermostatic A. Goldstein 981 998
Alloy magnesium zinc, W. Rubel 982 032
Alloys, making aluminium and copper J. G. & W. F. Mellen 982 218
Amusement device E. A. Napp 981,672
Animal trap G. Oneal 982,157
Article retaining means L. S. Adelson 981 005
Automatic regulator I. Wright Jr 982 026
Automobile attachment H. M. Carroll 981 914
Automobile controlling device, J. Eckhard 982 177
Automobile jack and tire rest L. C. Gracy 918,852
Automobile shipping case C. F. Fleming 982,046
Automobile wheel J. S. Draper 982 180
Axis indicator G. A. Bader 981 832
Axles, forming railway car T. H. Simpson 981 697
Babbitt material, J. L. Jones 981 767
Badge, J. E. Henry 982 060
Bag fastener W. Greene 982,178
Bag holder M. E. Hall 981 689
Baking pan F. P. Thien 981 717
Baling press, Gill & Graham 981 994
Bearing and bearing box E. R. Whitney 982,165
Bearing antifriction E. S. Woods 981 900
Bed and trunk combined, J. D. Waters 981,726
Bed bottom E. Ambrosy 981,966
Bed, sofa Karpen & Hultgren 918,926
Beds head rest for J. O. Ryan 981 691
Belt power conveying, E. C. O. Laird 982 073
Bicycle gear F. V. Whitman 981 729
Binder loose leaf J. Q. Adams 981 602
Binder music D. F. Magee 981 983
Binder separable H. G. Hasall 981 943
Bit brace bows, connection for E. A. Schade 981 698
Board See Ironing board
Boat attachment for drawing seines from the water N. O. Davidson 981 918
Boat bathing M. J. Ufford 982 025
Boiler cleaning device Smith & Mullihan 981 701
Boiler furnace water tube A. Smallwood 981 699
Boiler water purifying system steam W. P. Wiemann 982 107
Bolt anchor J. Kennedy 918 863
Book coupon S. H. Coates 928 127
Boring and routing machine H. Borgmann 981 743
Bottle capping machine, F. A. Thelen 981 817
Bottle closing device Eastrow & Snow 981,965
Bottle fillers jetting attachment for A. N. Ketterer 981 762
Bottle non refillable E. C. Wallace 981 827
Bottle soaking machine Wehmiller & Dawson 981 962
Bottle washing and soaking machine H. F. Stock 981 712
Bottle washing machine Wehmiller & Dawson 981 960
Brace, C. A. Burger 981 976
Braiding carrier tension, S. W. Wardwell 981 958
Braiding machine Parks & Wardwell 981 935
Braiding machine tension device Wardwell & Parks 981 957
Brake beam fulcrums making I. T. Handiges 981 645
Brake controlling apparatus plunger Baldwin & Furlow 981 909
Brake head adjustable I. T. Handiges 981 644
Brake shoe A. L. Streeter 981,896
Bricks machine for making hollow Brison & Hunter 981 839
Bridge, pontoon C. A. Forssell 981 991
Bridle safety D. Reed 982 159
Brooder E. D. Poston 981 942
Brooder fireless C. A. Dysle 981 986
Brooder for young chickens, self ventilating H. B. Young 982,196
Brooders, heating apparatus for W. B. McMeans 982,155
Broom hanger A. J. Mackey 981 777
Broom holder C. E. King 981,651
Buckle tug N. P. Petersen 982 090
Buffing or polishing wheel Codman & Worch 981 841
Building collapsible G. Fagman 981 992
Building construction F. Burcharts 982 030
Building earthquake proof O. Ruhl 981 884
Buildings in earthquake localities foundation for, F. Veres 981,824
Burner controller J. W. Dearing 981 844
Cable terminals hood support for E. L. Gravel 981 637
Cableway W. Hewitt 981 049
Can See Milk can.
Can end feed mechanism, A. Johnson 981 861
Can opener W. D. Priest 981,686
Cans, machine for packing caps in W. H. Robinson 982 092
Canning apparatus, C. A. Still Jr 981,812
Canning meat K. K. Schrader 981 694
Cane grinding machinery J. V. Hamilton 981 643
Car F. E. Stehm 982,108
Car brake R. V. Porter 981 941
Car brake, R. E. Wilson 981 963
Car coupling M. A. Brown 981 740
Car door Staley & Fletcher 981 709
Car door L. A. Sherman 982 099
Car door freight H. C. Percy 918,793
Car dumping righting and braking device, R. O. Keator 982 071
Car freight, J. W. Swarts 982,024
Car roof F. Horn 982 063
Car wheel C. J. Holcomb 982 179
Car wheel flexible, M. Magins 982,317
Carbureter L. P. Halladay 981,853
Cart device, hand, F. Ferguson 981,986
Casting chilled car wheels or other circular objects, mold for T. D. West 981 904
Cement post, H. D. Henion 982,137
Centrifugal machines, means for controlling electrically driven C. A. Adams 981 601
Chain clamp, L. M. Peddicord 982 019
Chain link, H. B. Hayward 982 058
Chalk line holder, G. Halleck 982 000
Chronograph, T. E. Fitch 981 969
Chuck for boring and turning mills, automatic, L. E. Vold 981,724
Churn, W. J. Hamblin 981 642
Churn, C. G. Mills 982,156
Cigar lighter electric Ekstrom & Boardman 981,967
Cigarette tipping machine, R. E. Molyneux 981,785
Circuit breaker Ball & Wright. 982 116
Circuit interrupter, H. B. Stuart 981 814
Clamp, F. C. Spanc 982,102
Cleaning tool and connection, L. H. Spangler 981,980
Cleansing and disinfecting fluid, A. M. Pyle 981,879

Clip, E. Whitlock 981,839
Cloth drying apparatus, M. B. Davis 981 621
Clutch, F. C. Sanford 981,665
Clutch, F. E. Millett 982 042
Clutch regulator P. M. Orloop 982 068
Cock, testing or priming B. Morgan 982 009
Coils and the like filter for G. H. Rupley 981 798
Coke ovens, leveling ram for L. Wilputte 981 732
Collar stuffing machine horse J. C. Collett 981 616
Commutators, oil guard for R. Siegfreid 981 808
Concrete block making machine G. W. Kramer 981,929
Concrete building block making machine G. W. Kramer 981 928
Concrete mixer A. W. Ransome 982 020
Concrete piling retaining wall structure M. M. Upson 981 822
Concrete water tank J. H. McCoy 982 080 982 081
Concrete work centering for L. G. Hallberg 982 055
Cooking utensil L. B. Felger 982 044
Cot, folding J. Moraff 981 878 981 874
Cots head rest for W. S. Ransom 981 688
Couch and bed convertible W. T. Jones 982 139
Coupling See Air brake coupling
Coupling carry iron F. Karel 982 005
Crane G. A. True 981 820
Cross tie and rail fastener metallic H. Christman 982 176
Cultivator W. F. Abercrombie 981,600
Cultivator and harrow disk C. W. Gardes 982 051
Cultivator disk journal E. B. Doyle 981 984
Current motor, J. H. Martin 982 154
Current potential switch alternating D. Larson 981 980
Curtain fixture C. L. Hopkins 982 002
Cutting board attachment L. B. Nicholson 982,065
Dam portable, E. A. Ernst 981 849
Dash brace R. L. Notman 981 936
Dental cleaning device G. B. Hakins 981 638
Derailing machine, D. W. Martin 982 158
Desk shelf swinging J. F. Collins 981 979
Desk tray J. B. Rowe 981 949
Detonator J. Harle 981 708
Dipper tooth V. W. Mason, Jr 981 606
Display apparatus electromagnetic W. A. Harvey 981 646
Display case A. W. Isom 981 851
Distilling oils of the petroleum tar and the like industries using a high vacuum apparatus for L. Steinschneider 981 953
Door check L. E. Hanson 982 136
Door construction metal, E. Ohnstrand 981 875
Door frame metal, E. Ohnstrand 981 937
Door pintle socket J. C. Regan 982 160
Door releasing device H. C. Bundy 981 913
Door securer G. W. Packard 981 017
Draft rigging friction J. F. O'Connor 981 675 981 700
Drawer pull M. & G. B. Kurtson 981 772
Drill C. H. Oslund 981 791
Drill attachment Whiteman & Chelsey 981 728
Drilling machine trip mechanism R. Milne 981 870
Drying plant hot air O. H. Phelp 981 719
Dye for wool yellow pyrazolone H. Geldermann 982 050
Dyeing compound and producing the same G. S. Whitty 981 104
Electric apparatus and operating the same vapor C. O. Bastian 981 110
Electric controller A. C. Eastwood 981 847 981 848
Electric drop light hanger Uhl & Barnhart 982 222
Electric machine dynamo W. F. Dawson 981 673
Electric metal working apparatus transformer for J. S. Lachman 981,669
Electric switch H. R. Sargent 981 692
Electric switch C. S. Van Nuis 981 823
Electric vehicle charging wall socket and plug J. N. Davis 981 6..
Electric vulcanizer Fish & Stanley 981 04.
Electric wiring fixtures outlet box supporting bracket for S. Adlman 981 110
Electrical apparatus heat dissipating means for H. A. Rhodes 981 880
Electrical motor H. A. Rhodes 981 881
Electrode frame and hanger C. B. Schoenmehl 982 097
Electrolytic cell J. B. Crocker 982 037
Electromagnetic switch alternating current D. L. Lindquist 981 931
Electromagnetically operated switch C. B. Larselere 982 146
Elevator cars electromagnetic braking mechanism for H. M. P. Murphy 981 671
Elevator control, traction R. C. Smith 981 806
Elevators, combined brake and cushioning device for traction A. Smith 981 807
Elevators safety slow down and stop motion for electric D. Larson 982 074
Embroidering machines, fabric frame for A. Bosshard 981 836
Emergency brake G. A. Morris 981 670
Engine. See Internal combustion engine
Engine cooling device G. W. Ike 981 733
Engine muffler, internal combustion O. C. Kreis Jr 981 770
Engine starting device A. C. Menge 981 868
Engine starting mechanism gas F. H. Glahn 982 133
Exhibitor automatic sign, W. Akin 981 880
Explosive V. I. Bedier 981 989
Fabric dressing apparatus Ratignier & Pervilhac 982 158
Fastener J. Jacomin 981 654
Faucet, H. G. Cordley 981 842
Faucet two-way F. Steiner 981 711
Faucets combined buffer nipple and filter for water M. H. Smith 981 702
Feed water heater E. T. Turner 981 901
Fence fabric wire G. E. Mirfield 982 185
Ferroboron producing C. A. Hansen 982 133
Filing cabinet, Weaver & Altenbaugh 981 959
Filing case W. K. Holman 982 002
Filling machine F. C. H. Strasburger reissue 13 197
Filtering material K. Kiefer 981 058
Fire means for protecting concrete or other structures from E. V. J. Hudson 982 210
Fishing stool C. F. Fraser 981 641
Flask See Molder's flask.
Flooring and sheathing clamp adjustable J. C. Moen 981 871
Fly escape A. J. Collar 981 180
Flying machine aeroplane Suman & Reichard 981 714
Folding mechanism O. Roesen 981 882
Food product forming a J. K. George 981 684
Fork handle auxiliary H. C. Langlois 982 145
Fruit juices, concentrating W. B. Jackson 981,860
Fuel saving appliance H. F. Nehr 981 673
Fungicide J. Stockhausen 982 162
Furnace forming die R. L. Williams 981 781
Garbage cart W. Nepean Hutchison 981 653
Garment clamp C. L. Robinson 981 946
Garment hanger Bell & Schlanger 982 120
Gas and separating its elements apparatus for liquefying E. F. Gallaudet 982 225
Gas and separating its elements liquefying E. F. Gallaudet 981,755
Gas burner C. Hoff 981 855
Gas burner incandescent O. Mannesmann 981 779
Gas generator grates, apparatus for and method of operating E. Hilger 981 651
Gas producer water B. Spitzer 981 706
Gases means for electric arc reactions on Weber & Schreiber 981 727
Gate fastener W. C. Neel 982 010
Gearing automatic reversing O. G. Pfeifer 981 940
Gearing frictional, M. Tarrisse 982 104
Glass tubes machine for shaping the ends of R. Koenig 982,212
Glove rack or holder Madden & Crouse 982,216
Governor C. E. Wright 981 064
Grab hook, safety, W. Breivogel 981 838
Grader road, J. T. Starr 981 710
Grading machine T. R. McKnight 981,781
Grading or sorting machine, G. Thomas 981 955
Grain and seed separator and cleaner O. W. Hall 982,807
Gramophone stop J. A. Johnson 982 138
Graphophones, electric brake for J. F. Means 982,000

Grinding machine A. A. Wood 982 166
Grindstone attachment D. I. Sterling 981 810
Gun lock multibarreled W. L. Marble 982 150
Guns, hammer for double barreled, W. L. Marble 982 152
Hacksaws, stroke adjusting mechanism for power Bradford & Olson 981 837
Hair drying, etc. machine for H. V. Halliwell 981 641
Hammer pneumatic A. H. Taylor 981 890
Handle R. J. Prins 982 220
Handle fastening W. A. Bradley 981 745
Handle or bail A. R. Pritchard 981,878
Hanger See Broom hanger
Harrow revolving J. Porteous 982 091
Harrow riding attachment R. R. Cyrus 981,982
Harvester cane A. Domingues 982 129
Harvester reel attachment F. O. Kullander 982 072
Hasp A. Voight 981 825
Hat pin E. C. Geneux 982 13.
Hauling tackle S. Ashdown 982 118
Hay loader B. A. Spinney 981 894
Hay press, F. W. Ekman 981 030
Headlight automobile Hunt & Vroom 981 000
Headlight vehicle J. M. Beaulieu 981 834
Hide stretching device J. F. Lee 982 147
Hoe blade, K. Skelly 981 098
Hog scalding trough J. A. Douglas 981 7 1
Hoisting apparatus safety device alternating current W. N. Dickinson 981 919
Holder, A. S. Langille 981 7 3
Hood for capes or other garments G. S. Andrus 981 738
Horn, electric J. Lanz 981 864
Horse detacher H. C. Langlois 982 144
Horse gag C. Lau 982 075
Horseshoe Buhs & Tillmanns 981 754
Horseshoe antislipping attachment S. A. Fritz 981 632
Horseshoe clip forming machine R. Grosdidier 981 999
Hose connection I. H. Spencer 981 700
Hose coupling S. R. Lockhart 981 860
Hose nozzle A. Trägning 981 950
Hosiery frame straight J. Lieberknecht 981 663
Humidity, regulating and maintaining H. D. Tiemann 981 818
Hydrocarbon motor A. B. Fowler 981 753
Ice cutting mechanism A. Day 982 040
Induction oil in asd H. C. Thomson 981 715
Inflatable article H. H. Caynor 981 040
Interlocking book fabric G. B. Smith 981 888
Internal combustion engine E. W. Stevens 981 811
Internal combustion engine C. Slintz 981 95.
Internal combustion motor C. J. ... 981 978
Ironing board sleeve H. M. ... 982 093
Irradiating apparatus holder for J. Rosenthal 981 948
Jointed figure A. Schoenhut 981 096
Jointing machine safety device W. A. Thoma 981 105
Key pad Dixon & Ireland 981 840
Knuckle combination power and steering H. W. Barger 982 117
Lamp W. T. Jones 981 927
Lamp automobile H. J. Knight 981 14.
Lamp control automobile W. F. Andersen 981 11
Lamp working apparatus, P. C. Jack 981,664
Lantern globe guard A. R. Ditchfield 981 879
Lantern globe lifting device W. I. & F. A. Iddings 982 181
Lasting apparatus W. B. Keighley 982 140
Latch D. C. Good 982 220
Lathe N. D. Chard 982 934
Lathe engine N. D. Chard 981 915
Lavatory attachment A. J. Lim 981 877
Leather working machine A. H. Kohrhahn 981 007
Life preserving belt F. J. Nekarda 981 788
Lightning arrester E. J. Berg 981 742
Lightning arrester R. P. Jackson 981 704
Lightning arrester E. E. F. Creighton 982 24
Lime hydrating machine E. E. Lypite 982 148
Linotype machine H. Degener 982 173
Lock. See Gun lock
Lock C. C. Chapman 982 125
Lock and latch combined H. Davis 981 843
Locket J. C. Daniels 981 917
Locket, L. E. Sadler 981 21
Locomotive electric N. W. Storer 981 13
Locomotive electric H. G. Bornstein 981 741
Locomotive electric W. Schaak 981 799
Loom, E. Gagnon 981 04
Loom attachment S. Kendrick 981 6 6
Loom beams supporting means for A. E. Rhoades 981 944
Loom Jacquard J. Jagger 981 706
Loom pattern mechanism carpet C. Hugo 981 70
Loom weft carter S. S. Jackson 981 859
Mail box E. D. Hale 982 200
Mail chute E. A. Fordyce 981 9 1
Mail tying device I. Allen 981 111
Malting apparatus for turning germinating grain in C. Schau 981 199
Manicuring implement A. A. Ewing 981 701
Manure carrier S. Jagger 981 069
Mast step H. B. Istrill 981 010
Matrix setting and line casting machine H. Degener 982 174
Measuring device W. B. Spencer 981 707
Measuring device fluid S. I. Nicholson 981 789
Medical radiator for use in ... Friall & Gallo 981 628
Mercury vapor apparatus J. T. H. Dempster 981 8
Metallic and glass construction Olsen & Damm 982 015
Metallic leaf in rolls machine for packaging C. E. Smith 981 700
Metalliferous materials treating C. F. Siegert 981 696
Methylene ethyl methyl ketone Merling & Kohler 981 069
Methylketobutanol Merling & Kohler 981 068
Milk can C. E. North 981 012 982 013
Milk separator M. Geller 981 758
Milking machine mechanism R. A. Wiggins 981 730
Milking machinery A. Small Jr 981 161
Mill See Pebble or ball mill
Mine cages and elevators safety mechanism for T. G. Baird 981 908
Mines safety appliance for H. W. Scheller 982 095
Molder's flask H. G. Voight 981 723
Molding machine M. E. Welch 981 903
Mop and scrubbing brush holder combined I. J. Glasley 981 756
Mop head and wringer combined Culley & Moore 982 084
Motion converting means Liais & Clammattel 982 077
Motor Godlove & Van North 981 995
Motor control W. N. Dickinson Jr 982 041
Motor control alternating current J. D. Ihlder 982 067
Motor suspension means electric C. A. Tallander 981 795
Mower lawn E. F. Pond 981 684
Mowing machine M. G. Otis 981 016
Music leaf turner W. A. Mattwig 981 790
Music spool adjusting and transposing device J. H. Ludwig 981 776
Nut lock S. Palmateer 981 678
Nut lock M. Hartl 982 118 982 .3
Oil burner H. N. Kellar 981 141
Oil burner C. W. Wright 982 167
Oil burner crude J. A. Scott et al 981 801
Oil can G. L. Neiburg 981 674
Oil can M. T. & W. C. Axtell 981 114
Oil press J. D. Belanger 981 870
Oiler automatic R. F. Adam 981 717
Oiling felloes device for J. W. Price 981 704
Ore separating apparatus centrifugal I. F. Peck 981 681
Ore separator centrifugal P. F. Peck 981 679 981 680 981 682
Ores, roasting sulfid W. W. Renwick 981 880
Outlet box F. I. Thayer 982 198
Ozone producing apparatus I. Glaser 982 227
Package J. F. Bowditch 981 744
Package carrier C. J. Miller 981 788
Package tie W. D. Smith 981 880
Package tie I. I. Canfield 982,081
Packing metallic W. M. Brooks 981 912
Packing, rod T. A. Johnston 982,188
Pad stuffing mechanism, Collett & Lause. 981,615

Padlock, C. M. Miller 981 784
Paint M. J. Waugh 981 902
Paper associating machine C. D. Curry 982 088
Paper associating machine feeding mechanism for C. D. Curry 982 030
Paper bag filling and closing machine E. Jagenberg 981,765
Paper box filling G. W. Gair et al 981 983
Paper hanging device wall M. F. Randle 981 687
Paper machines double facer for corrugated J. Duufe 982,176
Paper package machine for forming W. Barrett 981 607
Paper preparing fibrous materials for the manufacture of, G. D. Burton 982 170

Electrical Notes

Large electromagnets have been employed by ocu lists for more than twelve years, for the removal of splinters of iron and other magnetic metals that have entered the eye Two French surgeons regularly and successfully employ a very powerful electromagnet for the extraction of needles and similar foreign bodies from the tissues in general The needle—it is usually a needle—is first located very accurately by means of two X-ray radiographs taken in different planes. The electromagnet being then applied to the skin, in the most favorable position draws the needle to the spot and causes it either to emerge through the skin or to produce a little conical elevation of the skin. In the latter case it is necessary to make an incision less than half an inch in length in order to allow the needle to escape from the skin

Prof. Lippmann of Paris has been making researches upon electric contacts and finds that he can produce a contact without using pressure This may prove of great service for relay work as the problem in mak ing a sensitive relay consists in securing enough pressure to make the contact. It is known that when two metal pieces are in contact, a certain pressure is needed in order to make the current pass even when gold or platinum is used This causes the diffi culty in making a relay to work on very small cur rents as we cannot have sufficient contact without much difficulty Prof Lippmann sought to obtain a contact which would work without any pressure, and succeeded by using a metal on one side and an elec trolyte on the other A chloride of calcium solution answers very well and he uses a strip of letter paper wet with the solution and applied against a glass strip which serves as a support, immersing the lower end in a vessel containing the liquid so that part of the paper projects above The solution serves to keep up the moisture and it also brings the current to the paper He finds that the slightest contact between the paper and a metal piece is enough to make an electric contact This is proved by taking a gold leaf piece for the metal part. A galvanometer or relay in the circuit always works in this case and as the gold leaf is too flexible to give any appreciable pressure, the result is striking. Should a large surface of metal be used such a contact would stick and re quire some force to separate it. In some cases this would not be a disadvantage but in others the con tact surface should be small As to the use of mer cury it is known that a wire must be dipped well into the mercury in order to make an electric con tact However two amalgamated silver wires will make contact without pressure on the above principle provided the surface is kept wet with mercury

According to a note in *The Electrician*, a standard gage light railway at Gummersbach has recently been electrified The railway is intended principally for goods and carrying ore, but there will also be a few passenger trains High tension three-phase current at a pressure of 10 000 volts and a frequency of 50 will be obtained from the local electricity works and transformed by two 150-kilowatt motor generators to con tinuous current at 750 volts for supply to the trolley wire The railway is ten miles long the maximum distance from the transformer station being five miles The goods consist for the most part of stone from the stone quarries, which is only carried in one direction, so that only fairly empty wagons have to be drawn against the gradient. Owing to this circumstance the average consumption on the continuous-current side is only 160 watt-hours per ton-mile. The goods trains, which consist of six standard open wagons, are drawn by locomotives weighing 20 tons and fitted with two [illegible] horse-power motors, without causing any great variation of load at the transformer station. A comparison between the two systems of working—steam and electricity—shows that the latter is more efficient.

Alcohol

Its Manufacture
Its Denaturization
Its Industrial Use

The Cost of Manufacturing Denaturized Alcohol in Germany and German Methods of Denaturation are discussed by Consul General Frank H Mason in SCIENTIFIC AMERICAN SUPPLEMENT 1550

The Use, Cost and Efficiency of Alcohol as a Fuel for Gas Engines are ably explained by H Diederichs in SCIENTIFIC AMERICAN SUPPLEMENT 1596 Many clear diagrams accompany the text The article considers the fuel value and physical properties of alcohol and gives details of the alcohol engine wherever they may be different from those of a gasoline or crude oil motor

In SCIENTIFIC AMERICAN SUPPLEMENT 1581 the **Production of Industrial Alcohol and its Use in Explosive Motors** are treated at length, valuable statistics being given of the cost of manufacturing alcohol from farm products and using it in engines.

French Methods of Denaturation con stitute the subject of a good article published in SCIENTIFIC AMERICAN SUPPLEMENT 1599

How Industrial Alcohol Is Made and Used is told very fully and clearly in No 3, Vol. 95, of SCIENTIFIC AMERICAN

The Most Complete Treatise on the **Modern Manufacture of Alcohol**, explaining thoroughly the chemical principles which underlie the process without too many wearisome technical phrases and describing and illustrating all the apparatus required in an alcohol plant is published in SCIENTIFIC AMERICAN SUPPLEMENTS 1603 1604 and 1605 The article is by L Baudry de Saunier, the well known French authority

In SUPPLEMENTS 1607, 1608 1609 we publish **a digest of the rules and regulations** under which the U S Internal Revenue will permit the manufacture and denaturation of tax free alcohol

A Comparison of the **Use of Alcohol and Gasoline in Farm Engines** is given in SCIENTIFIC AMERICAN SUPPLEMENTS 1634 and 1635 by Prof Charles F Lucke and S M Woodward.

The Manufacture, Denaturing and the Technical and Chemical Utilization of Alcohol is ably discussed in the SCIENTIFIC AMERICAN SUPPLEMENTS 1613 and 1636 by M Klar and F H Meyer, both experts in the chemistry and distillation of alcohol Illustrations of stills and plants accompany the text.

The Source of Industrial Alcohol, that is the Farm Products from which alcohol is distilled, are enumerated by Dr H W Wiley in SCIENTIFIC AMERICAN SUPPLEMENTS 1611 and 1612 and their relative alcohol content compared

The Distillation and Rectification of Alcohol is the title of a splendid article by the late Max Maercker (the greatest authority on alcohol) published in SCIENTIFIC AMERICAN SUPPLEMENTS 1627 and 1628. Diagrams of the various types of stills in common use are used as illustrations

In SCIENTIFIC AMERICAN SUPPLEMENT 1613 the **Uses of Industrial Alcohol in the Arts and in the Home are discussed.**

Any Single Number of the SCIENTIFIC AMERICAN or SUPPLEMENT will be sent for 10 cents by mail The entire set of papers above listed will be mailed on receipt of $2 00

Trade Notes and Formulas

The following recipes and formulas are published simply as suggestions Chemicals vary, for which reason it is not always possible to comply with the conditions stated, or for us to guarantee the accuracy of the recipes A little experimenting, however, will easily enable the interested reader to ascertain just what modifications are necessary to meet his requirements —Editor of SCIENTIFIC AMERICAN SUPPLEMENT

Weather Foretelling Pictures.—Production 1 part chloride of cobalt 10 parts gelatine, 100 parts water, which gives blue color, 1 part chloride of copper, 10 parts gelatine, 10 parts water, for yellow, 1 part chloride of cobalt, 0 75 part nitrate of nickel, 0 25 part chloride of copper 20 parts gelatine and 200 parts water gives green Soften the gelatine in water, add the preparations and melt over a gentle fire

To Mark Tools.—Coat the tools to be marked with a thin covering of wax or hard tallow by heating the steel, rubbing the wax over it while warm until it melts and then allowing it to cool Now scratch the mark in it with a sharp instrument and pour on nitric acid rinsing the acid off with water after a time finally heat the metal until the wax melts and wipe it off The mark appears as though engraved.

Manifolding Drawings and Documents (according to Alfred Astfalck) —A sheet of paper blackened with iron gall nut ink and moistened with sulphate of ammonia, is covered with another sheet on which is written or drawn with ink that is a non-conductor of electricity Both sheets, between conductive plates are exposed to an electrical or galvanic current and the first sheet is then washed with water The effect is produced by the electrolytic decomposition of the ink

To Transfer and Fix Drawings on Ivory and Vegetable Ivory —The picture to be transferred is printed as a negative by lithographic process in a black fatty ink on a paper prepared for transferring in the well known manner By transfer printing the picture is placed on the article to be decorated The latter is rinsed in clean water and finally light being excluded is passed through a solution of nitrate of silver, then exposed to the effects of daylight. The parts free from fatty color are thereby tinted dark, the black color is washed off with exclusion of light by rectified oil of turpentine and the object immersed in a solution of hyposulphite of soda. Various colors may be obtained by the use of different substances sensitive to light, and by the use of baths of varying strength

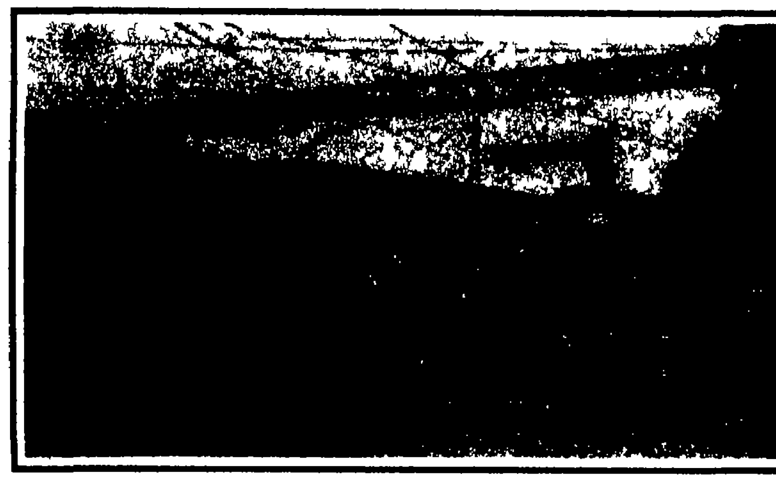
VIEW IN ROTUNDA HALL AT ST LAZARE DEPOT OF NEW PARIS SUBWAY

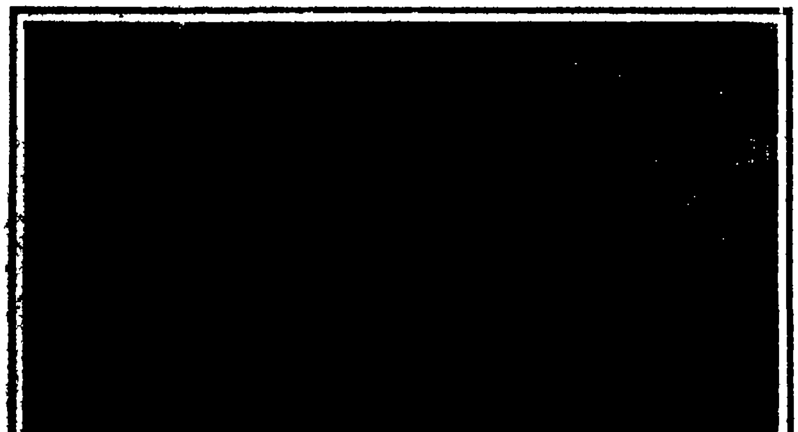


PARIS COMMISSION OF CONTROL VISITING NEW NORTH SOUTH SUBWAY VIEW OF YARDS SHOWING TRAIN

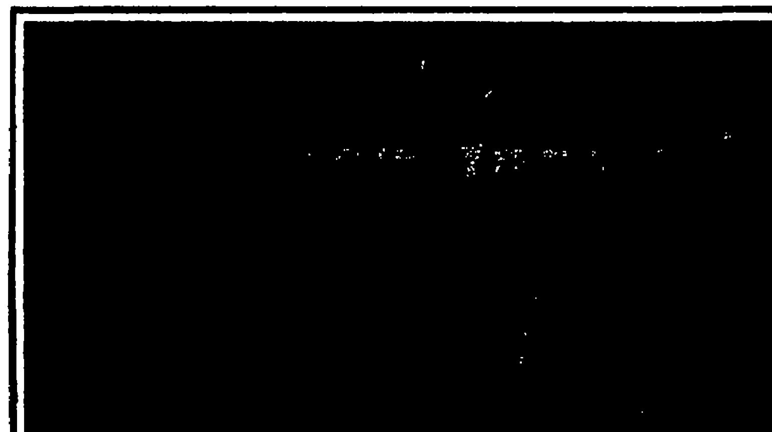
TUNNEL UNDER THE SEINE STARTING POINT OF THE TWO TUBES, SHOWING UNDERGROUND STATION

BERLIER TUBE OF PARIS SUBWAY UNDER THE SEINE

CONSTRUCTION WORK BERLIER TUBE THE WATER DRIVEN PUMPS



... OF SUBWAY STATION, SHOWING PLATFORM ON EACH SIDE OF DOUBLE TRACK, STANDARD TUNNEL TROLLEY WIRES, THIRD RAIL EXIT AT RIGHT ETC



SHIELD OF BERLIER TUBE CONSTRUCTION OF NEW PARIS SUBWAY

THE NEW PARIS ELECTRIC SUBWAY

A New Electric Subway in Paris

The North-South Line

By the Paris Correspondent of the Scientific American

Paris now has a new line of electric subway in operation and it is likely to prove a favorite with the public While it is laid out on about the same general plan as the Metropolitan subway whose different sections run through the city it was constructed and operated by an entirely different company As regards the tunnel work of the line which is known as the North South subway we would refer to an account which we previously published at the earlier stages of this construction illustrating the steel tube tunnel running under the Seine We also present some views which were taken of the tunnel and other parts of the work at a later period than those accompanying our former article The remainder of the views showing the subway in its finished state the trains etc were taken at the time of the official inauguration of the line early in November On this occasion the Prefect of the Seine and delegates representing the ministerial department of public works the Municipal Council and other official bodies made a visit to the line and on the following day it was opened to the public

For most of the way there is used a double track tunnel the tracks being standard gage and employing the third rail system for taking the current Each track however runs in a separate tube when passing under the Seine In addition to the third rail an overhead wire is run along the tunnel and the motor cars are run by trolley as well as on the third rail system Short side tracks are placed at intervals in the tunnel which is here enlarged to receive them so that in case of obstruction to the track the trains will not be stopped in the main part of the tunnel but can be sidetracked

It will be remembered that the North South line was organized on an entirely different financial and operating basis from the regular Metropolitan subway Some years ago the plans for the Metropolitan were drawn up so that when finished it would cover the whole town by its different sections as nearly as this could be realized When entirely completed which will take several years to come there will be no less than 70 miles of subway in operation However it was noticed that a gap had been left in certain quarters of the town and it would be desirable to cover this so as to connect the southern quarters of Vaugirard and Montparnasse with the northern quarter of Montmartre For this reason the North South company was formed quite outside the Metropolitan system in order to have the new subway constructed more rapidly than would otherwise have been the case

The total length of the line when finished will be about 9 miles At present it ends shortly after the St. Lazare railroad depot and the remainder is at present in construction There are now finished 18 stations starting from the Versailles Gate and running by the Montparnasse Depot crossing the Seine at the Place de la Concorde and reaching the St Lazare Depot. When completed there will be 30 stations in all It was specially desired to connect the two railroad stations so as to give a more direct transit between these two points

Profiting by the experience already obtained in running the older subway during the last few years the North South line has a number of minor improvements which will be appreciated by the public The cars did not need to be changed over from single truck to double bogie as was the case for the Metropolitan line and involving considerable expense as did also the adoption of fire-proof motors after the very disastrous fire at the Couronnes station where so many passengers lost their lives by being smothered by the smoke from the burning train In the present case the cars are run from the start upon double bogie and all the most recent improvements have been made in the motors and controling apparatus The motor cars are built on the plan which follows the most approved practice that is the cabin is located at the car end and is quite partitioned off from the rest of the car with a small access door The remainder of the car is devoted to seating and standing places, on the central passage system following about the same plan as for the other subway Motor cars and trailers go to form the train the trailers differing only in the absence of the cabin Good lighting and ventilation add to the attractiveness of the cars The first and second-class cars have scarcely any difference except that they are painted outside in buff and blue color respectively

A general elliptical section is given to the stations and they are reached by staircases which descend from openings in the pavement These openings cannot be housed over as a general rule owing to the obstruction which they would give to the view Some difficulty was found in the old line in obtaining a suitable non slipping material for the steps when they were made wet by rain For the new line pressed carborundum has been used for this purpose It is very durable and at the same time excellent in preventing slipping As the line crosses the different sections of the other subway at four different points it was required to make the transfer in the proper manner so that passengers can go from one line to the other

Each subway has a separate station and these are connected by underground passages No extra charge is made in any case for the transfer the price of tickets being 3 cents for second class and 5 cents for first class on both lines Before 9 o clock there are delivered to employees return tickets for 4 cents, which allows of a return at any time of day

At the St. Lazare railroad depot there has been constructed an underground rotunda hall which is used as a centering point for the numerous passageways These are needed for the two subway stations, the passage leading to the railroad station and the street entries and exits One part of the rotunda is here represented It is surrounded with recess windows which are to contain displays of different kinds. In the center are the ticket offices and newstands The hall has a vaulted ceiling upheld upon columns and its design is tastefully carried out Another station at the Rue Falguière is worthy of remark from the fact that it is built of reinforced concrete We have already illustrated this work and it will be remembered that the present material was adopted on account of the narrowness of the street between the house foundations The side walls of the elliptical station had to be very thin in order to keep the same standard inside space The problem was very well solved by the use of reinforced concrete so that a side wall of but 0 61 meter (2 feet) could be employed

The stations are lined with white enameled brick and the name of the station is shown in large letters of colored brickwork Owing to the difference in the colored brick trimming of the station green or brown passengers can see at a glance which are the stations for making transfers The present tunnel does not run in a loop at the terminals as before but the trains are simply reversed these being adapted for running either way One of our views shows the train at the station yards which lie outside the tunnel near the Versailles gate A somewhat novel feature is the use of a combined third rail and overhead trolley system for operating Here the third rail is insulated and carries one side of the current while the other pole of the current is connected to the overhead wire using the ground (or track rails) as the common return

This gives a three-wire system and 1 200 volts are used in all in order to operate the two 600 volt motors of a car in the same way as two 110-volt lamps are coupled upon the 220 volt three-wire system In the case of the two motors one side of motor No 1 is thus connected to ground or the track rail and the other side to the third rail Motor No 2 is connected on one side to ground and on the other to the trolley wire The load is about even on each motor owing to the controller combinations By this method 1 200 volts are used on the current mains and consequently on half the current for the same power as if 600 volts were used and this reduces the size of the wiring

---

RULES GOVERNING THE COMPETITION FOR THE $15,000 FLYING MACHINE PRIZE OFFERED BY MR EDWIN GOULD

1 A prize of $15 000 has been offered by Mr Edwin Gould for the most perfect and practicable heavier than air flying machine designed and demonstrated in this country and equipped with two or more complete power plants (separate motors and propellers) so connected that any power plant may be operated independently or that they may be used together

CONDITIONS OF ENTRY

2 Competitors for the prize must file with the Contest Committee complete drawings and specifications of their machines in which the arrangement of the engines and propellers is clearly shown with the mechanism for throwing into or out of gear one or all of the engines and propellers Such entry should be addressed to the Contest Committee of the Gould-Scientific American Prize 361 Broadway New York City Each contestant in formally entering his machine must specify its type (monoplane biplane helicopter etc) give its principal dimensions the number and sizes of its motors and propellers its horse-power fuel-carrying capacity and the nature of its steering and controlling devices

3 Entries must be received at the office of the Scientific American on or before June 1st, 1911 Contests will take place July 4th 1911 and following days At least two machines must be entered in the contest or the prize will not be awarded

CONTEST COMMITTEE.

4 The committee will consist of a representative of the Scientific American a representative of the Aero Club of America and the representative of some technical institute This committee shall pass upon the practicability and efficiency of all the machines entered in competition and they shall also act as judges in determining which machine has made the best flights and complied with the tests upon which the winning of the prize is conditional The decision of this committee shall be final

CONDITIONS OF THE TEST

5 Before making a flight each contestant or his agent must prove to the satisfaction of the Contest Committee that he is able to drive each engine and propeller independently of the other or others and that he is able to couple up all engines and propellers and drive them in unison No machine will be allowed to compete unless it can fulfill these requirements to the satisfaction of the Contest Committee The prize shall not be awarded unless the competitor can demonstrate that he is able to drive his machine in a continuous flight over a designated course and for a period of at least one hour he must run with one of his power plants disconnected also he must drive his engines during said flight alternately and together Recording tachometers attached to the motors can probably be used to prove such performance

In the judging of the performances of the various machines the questions of stability ease of control and safety will also be taken into consideration by the judges The machine best fulfilling these conditions shall be awarded the prize

6 All heavier than air machines of any type whatever—aeroplanes helicopters, ornithopters, etc.—shall be entitled to compete for the prize but all machines carrying a balloon or gas-containing envelope for purposes of support are excluded from the competition

7 The flights will be made under reasonable conditions of weather The judges will at their discretion order the flights to begin at any time they may see fit, provided they consider the weather conditions sufficiently favorable

8 No entry fee will be charged but the contestant must pay for the transportation of his machine to and from the field of trial

9 The place of holding the trial shall be determined by the Contest Committee and the location of such place of trial shall be announced on or about June 1st 1911

Lieut. Bouvet has been making excavations at the Roman *castellum* of Ras-el-Ain Tlalet in the North African region owing to a subsidy received from the Tunis archæological department It is a fortified place of square shape of about 200 feet on a side The walls are 5 feet thick and are rounded at the four corners like the fort of El Hagueuf Doors are observed on the north and south sides, but not in the center The construction resembles that of the ancient camps of the Roman legion. Cavities below the ground level are found which appear to be Christian tombs. One of these 7 feet deep, contained a square pitcher and a Christian lamp Probably the tombs were violated in ancient times. A chamber resembling a cellar was also found, and it contained the débris of about thirty amphoræ with numbers printed on them Lamps, coins, and vases were found in this place.

The Armament of Battleships

Sir William White s Views

THE general principles of warship designs belong to no one nation. It needs however the practical as well as the theoretical experience of past years gained both at sea and in office of experimental work afloat and ashore and of design work tempered by the judgment of its unbiased users to produce a ship especially one for purposes of war in which every thing is not only placed to the best advantage but which shall simultaneously possess the important quality of fighting power associated with peace time convenience and habitability Just at the present moment when the competition in naval armaments has pressed to the very utmost the output resources of the great armament firms in England Germany and the United States the views of Sir William White, as they appear in an interesting paper on the subject of battleship armaments to the Society of Naval Architects and Marine Engineers in New York are of more than usual interest Sir William has probably designed more warships than any other naval architect and his views have invariably been expressed with a temperate logic that goes far to carry conviction in the face of marked and able differences of view enunciated more emphatically but almost inevitably based on shorter experience of the subject under discussion Sir William s views in his latest paper indicate very clearly that his reputation for clarity of exposition has lost none of its force since he resigned the position of Chief Constructor to the Royal Navy

The arguments in the paper under discussion reflect very fairly the views of the two camps into which gunnery schools may be said to be divided One is the all big gun one-caliber school while the other advocates a secondary armament for battle purposes As Sir William points out at the beginning of his paper the fundamental idea which has governed the armaments of warships in all ages is the desire to provide means of offence which will enable a ship to destroy her adversary in the shortest possible time with the minimum damage to herself and active offence still constitutes the best though not the only means of doing so The best arrangement of armament for this purpose is discussed largely on the lines of Sir William s criticism of Admiral Bacon s paper on the Battleship of the Future read before the Institution of Naval Architects in London early in 1910 and more space being at his disposal on this occasion the pros and cons of the Dreadnought type are comprehensively analyzed and deliberate opinions expressed as a result Let it be said at once that Sir William advocates the re adoption of the 6 inch gun as a fighting weapon in association with not more than four twin center line turrets arranged as in the South Carolina an arrangement which it is said is to be adopted in the new Japanese battleship now being built at Barrow Whether the big gun advocates will believe that in the latter case the secondary armament is for fighting or for anti torpedo boat purposes is another matter Their view was given in these columns some few weeks ago in a leading article on the resuscitation of the medium caliber weapons

It is generally agreed that battle ranges have inevitably increased of late years owing to the development of the locomotive torpedo and to systems of fire control associated with improved gunnery Conflicting views are held as to what the range will be Climatic conditions and a serious intention of attaining a decisive issue may tend to reduce the range that would be chosen by the faster all big gun ships Herein lies the crux of the situation When the earlier Dreadnoughts were built their speed gave them the advantage of choosing the range Now that there are numerous ships of this type as well as much faster torpedo craft afloat there is as we pointed out in the article referred to a strong tendency to develop the smaller weapons But for what purpose? Not for battleship attack directly For indirect attack for keeping up a blanketing' fire with the object of making it difficult for the enemy to see the attacking ship and on the off chance of their effecting damage to unarmored structures and communications which in fluence fighting efficiency they may be useful but it becomes a question as Admiral Bacon said as to whether adequate value for tonnage involved is obtained by their adoption Obviously if they are installed at all they can be used for any or all purposes as long as they remain in action The volume of fire obtainable from such quick firing would some say inflict considerable damage and the experience of the Russians at Tshushima is generally dragged in to prove it It is in this case Well in Capt Semenoff's book quoted in the paper under review we find on page 124 the remark That s only a 6 inch no more portmanteaux now' —the word referring to the Japanese 12-inch shell Again on page 135 There was a loud crash this was not a 6-inch shell, but the portmanteaux again The men became seized with panic Semenoff tells ably of the utter destruction due to shell fire but his words are apt to be misread the heavy shell was what they feared and a similar well directed fire from the Russian ships—secondary or primary or big torpedo —would have kept the Japanese much farther away obviously leaving the action even more to a question of portmanteaux With this practical experience in view it is impossible to reconcile Sir William s reason for believing that actual trials do not confirm the objection to mixed armaments on the ground that the simultaneous discharge of guns of different calibers must be accompanied by diminished efficiency in the control of fire and in the proportion of hits to rounds made by guns of different calibers As we stated some time ago when gun fire is handled so as to obtain hits not merely volume of fire the rapidity of discharge is much below the possible rapidity of fire of the gun Admiral Bacon suggests that it is merely a quarter of the potential rapidity and aptly remarks that rapidity of fire unaccompanied by rapidity of hitting is a futile waste of ammunition We hold most strongly that in the King Edward class for instance the accuracy of 6 inch fire is materially affected by the simultaneous discharge of the 9 2 inch and 12 inch guns It suffers also in rapidity from the smoke nuisance

In referring to the number of heavy guns to be mounted Sir William advocates pairs and goes on to note the extraordinary Italian practice of mounting three triple and two twin turrets in the Dante Alighieri class Triple turrets involve insuperable objections to practical gunners of the hit the target order besides being too many eggs in one basket they suffer from smoke interference and throw off to an excessive extent The relationship of protective material and the adequate support of the same also receives attention In many foreign vessels we find turret roller paths fixed directly to or supported on the vertical barbette armor—a most dangerous practice as in action the combined efficiency of the heavy gun armament in spite of heavy blows on the protective armor is a primary consideration Adequate clearance between fixed and moving portions of a turret should always be allowed in spite of the increased overall dimensions and weight necessary Reference is made to the maximum number of heavy guns that should be carried by a warship Here the author is on much safer ground In tonnage value for effect obtainable it is hard to believe that it is possible to improve on the arrangement first adopted in the United States battleship Michigan of four twin turrets on the center line the two inner turrets firing over the two end turrets Such an arrangement possesses the great advantage of minimum interference between turrets due to 'blast The system adopted in the Inflexible class in the Von der Tann or the Spanish battleships of having two center line and two echelon turrets really reduces these vessels in practice to the status—considering broadside work only—of six gun ships On paper the echelon arrangement allows three pairs of turrets to fire ahead and astern on the keel line On board such a discharge causes unpleasant consequences and the limits of safe training in practice are considerably less than the extremes shown on the drawings Of course automatic danger signals —generally shrill buzzers by the side of the turret training levers are supposed to warn the gun layer when he risks his own or his neighbor s comfort from blast but these are extremely apt to be unreliable in action and the system of mounting guns to avoid this even if the number of heavy guns be reduced will probably be found best in service The advantage conferred by confining the primary armament to the ends of a ship as far as magazine accommodation is concerned is very considerable Side turrets as in the Dreadnought or Minas Geraes are inconvenient—the Nassau is very bad with four large turrets crowded together owing to the difficulty experienced of making a good boiler and engine room arrangement Sir William does not touch on the point beyond referring to the objection to mixing stokeholds and magazines but it entails probably an additional row of boilers to make up for the staggered units cut out by an echelon arrangement or an increased length over the machinery space to allow for a transverse magazine This involves a corresponding addition to the length weight and cost of the heavy belt armor In view of this and the question of interference his deliberately expressed convictions that in no case is it desirable to mount more than eight heavy guns in a single ship and that these are best arranged in four positions as in the Michigan class will meet with less criticism than his third view that they should be supplemented by a powerful and well protected secondary armament

A large number of naval officers want a protected 6 inch battery reintroduced in spite of their expressed conviction that its fire may be discounted at ordinary battle ranges when accompanied by a 12 inch gun fire Here is where Sir William takes an opposite view A secondary battery mounted as in the Michigan on the upper deck is in our opinion vastly better than the corresponding main deck battery of the Delaware With however the smoke nuisance from the heavy guns the continual anticipation of blast effect from overhead and the lower rate of fire inevitable from these causes as well as from the desire for accuracy it is hard to agree with him The naval desire for the reintroduction of the 6 inch gun arises from a belief that it is a better anti torpedo gun than the 4 inch Opinions on this point also differ widely If the increased caliber of heavy guns tends to put up battle ranges then it probably is but as we stated in the article we referred to the 4 inch should also be retained in our opinion for mounting in the superstructure

At the conclusion of his paper Sir William turns to the important point of future gun caliber and draws a trenchant parallel between present practice and that of twenty years ago All the arguments that held good for the increase from 12 inch to 13 5 inch hold good for an early advance to 15 inch or 16 inch Such a gun is being made we believe at the present time No argument is raised against such a caliber except that of larger or more costly ships This has never been heeded Warships of all kinds are generally smaller than merchant vessels and for many years the largest have never exceeded about 60 per cent of the greatest mercantile displacement There are at present at least four ships being built with over 60 000 tons full load displacement and an increase in war ship size is inevitable in the early future So it is with speed The Von der Tann and Lion will set examples of a far reaching kind Nothing is said of the tactical influence of speed or armament in the paper under review but it is obviously considerable Meanwhile in spite of Sir William s generous treatment of the subject we feel assured that the big gun school adhering to the results of their practical experience will remain unconvinced that for fighting purposes anything less than the biggest convenient gun is worth having —*The Engineer*

MR. H E. WIMPERIS M.A Assoc M Inst. C E before the British Association for the Advancement of Science described the form of accelerometer recently invented by him The instrument consists of a brass box about 4 inches across containing a copper disk mounted on a vertical pivot and damped in its motions by a permanent magnet. The c.g of the disk is purposely removed from the axis so that when the box moves forward one side of the disk tends to lag behind thus partially winding up a coiled spring and actuating a pointer which moves over a scale To render the reading unaffected by any accelerations at right angles to the direction of motion a second parallel axis is fitted which is geared to the first one and has attached to it masses having the same mass moment as the disk itself Couples about these two axes add up in the direction of motion but neutralize one another in any direction at right angles The accelerometer therefore reads in one of the three directions of space only and is not affected by even violent movements in the other two directions With this instrument the author has measured the road resistance of various classes of road and has obtained figures varying from 50 pounds to 210 pounds per ton On main line railways the resistance is usually from 12 pounds to 20 pounds per ton depending on the speed Measurements have also been made of the resistance to motion when a motor car is coasting In this way the horse power and the engine friction can be measured and a figure for the mechanical efficiency be obtained

The conclusions reached may be summed up as follows By the use of the accelerometer road resistances can be read off at sight the air resistance of the various shapes of car body can be determined the brake horse power and indicated horse power of the engine can be obtained for various speeds and that it is possible to trace step by step the losses of power in transmission to the road wheels

Some Notes on Telephony*

Facts and Principles Underlying Modern Practice

By H Harrison, '07

I

In writing this article it is my object to bring together concisely such fundamental and general information pertaining to telephony which is not readily available to the technical man not directly engaged in this phase of engineering activity

Of the many telephone systems in operation no one can be said to typify universal practice Each has some peculiarity which renders it especially adaptable for some particular situation not possessed by the other Fundamentally however all of the systems are alike it is only in the devices employed to get successful results that practice varies so widely With this in view the text circuits and sketches will aim to emphasize general principles only

II

Any variation of resistance in a circuit will pro-

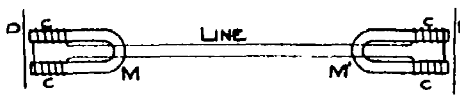


Fig 1

duce a variation of current upon this principle depends the successful electrical transmission of speech The *variation of current* is the essential point Fig 1 illustrates this M and M are both permanent magnets The coils cc and cc are wound around the ends of these magnets and are connected in series with the line D and D are soft iron diaphrams Normally the magnetic flux produced by M and passing through the coils cc remains unchanged Any change in this magnetic flux will induce an electromotive force in cc and this in turn will produce a current in any circuit with which cc may be connected Voice waves upon striking D will cause it to move to and fro thus varying the distribution of the magnetic flux set up by M and producing currents in cc These currents will vary (1) in strength according to the intensity of the motion of D and (2) in direction according as D is moving toward or away from M Such a *variation of current* in cc will cause the magnet M to be correspondingly strengthened and weakened thus exerting a varying pull on D and reproducing the original voice waves faithfully

In the scheme outlined above the talking currents are produced by virtue of the transmitter acting as a generator or dynamo the power for driving the dynamo being derived from the particles of air engaged in constituting the sound waves The currents so produced must of necessity be very weak and therefore only effective for comparatively short lines To overcome this defect a transmitter has been devised which depends for its action on causing variation in the strength of a current generated by an outside source The variation of current is obtained by making use of the principle that if the pressure between two conducting bodies forming part of an electric circuit be varied the resistance of the path between them will also be varied Fig 2 illustrates this

The current from the battery passes through the

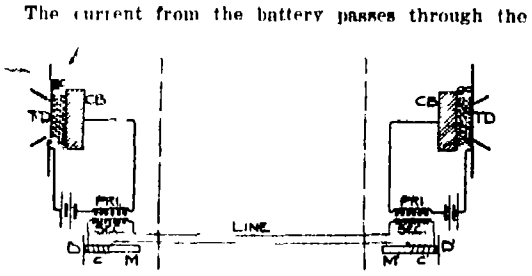

Fig 2

primary of an induction coil and through a mass of granular carbon gc which lies loosely between a carbon block CB and the diaphragm TD Any sound waves striking TD will produce a slight to and fro motion of the diaphragm which will cause the resistance of gc to vary This variation of resistance will cause corresponding changes of current in the primary circuit thus inducing currents in the secondary which pass over the line and affect M and M' (both acting as receivers) as has been explained under Fig 1

It might be well at this point to call attention to the fact that the varying current in the primary of the induction coil is undulating in character and always in the same direction The secondary current is however alternating in character its direction depending on whether the primary current is increasing or diminishing in strength Then again by virtue of the large size of wire and the small number of turns in the primary winding of the induction coil and the comparatively small size of wire and the large number of turns in the secondary winding a comparatively high voltage is available with which to send the talking currents over long lines of high resistance

Fig 2 embodies all the elements essential for the effective transmission of articulate speech There is lacking however a signaling system so that an individual at one instrument can call the attention of an individual at another instrument in the same system when communication is desired For such a purpose the magneto hand generator in circuit with a polarized bell is very largely used and affords a most reliable signaling apparatus Fig 3 illustrates this

The magneto hand generator is an alternating current machine depending for its action on the principle governing the action of all dynamo-electric machines i e that if the number of lines of magnetic force passing through a closed coil be varied currents of electricity will be generated in this coil the direction of these currents depending upon the direction of the lines of force and on whether their number is decreasing or increasing

The armature A is wound with a large number of turns thus permitting the variation in the number and direction of the lines of magnetic force that pass through it in its various positions as the crank C (Fig 4) is turned The lines of force are produced by the permanent magnet NS (Fig 3)

The bell shown in Fig 3 is a polarized bell NS is a permanent magnet c and c are soft iron cores connected by the yoke y also of soft iron and on which the bell caps are mounted The bell hammer is rigidly fixed to A which is so pivoted that its ends may move freely toward c or c according to which is the stronger magnet The alternating current from the magneto periodically strengthens and weakens the magnetism induced in c and c by NS so that one end of A is alternately attracted more strongly than the other which makes the hammer strike alternately the two bell caps

The bell and the armature winding are connected in series with the line (see Fig 5) Hence any ringing current coming from the line meets the resistance of the magneto This resistance which is appreciable would weaken the ringing current considerably To remedy this special devices are provided which short circuit the armature when the magneto is not in use

Fig 4 illustrates this Here the short-circuit is made between p and p by the contact at d which is held in place by a spring As soon as the crank C is operated p' is pressed away from p by means of another spring When C has ceased to turn the short circuit is re established

III

Enough has been said to make plain along what lines certain fundamental electrical principles have been utilized in telephony By way of emphasis a brief summary will prove useful

Prof A G Bell is given the credit for constructing the first successful telephone instrument His success was due in a great measure to the fact that he realized fully the importance of a basic principle announced at the time by Lord Kelvin viz that If electricity is to convey all the delicacies of quality which distinguish articulate speech the strength of its current must vary continuously as nearly as may be in simple proportion to the velocity of a particle of air engaged in constituting the sound The make and break principle used by many experimenters could not be made to meet the above requirements To get a current which would vary continuously and in simple proportion to the velocity of sound Bell made use of two electrical principles (as explained under Fig 1) (1) that, if the intensity of a magnetic field inclosed by a conductor be in anywise varied a corresponding varying current of electricity will flow in said conductor (transmitter) and (2) that if a permanent magnet be under the influence of a varying current this current will, according to its direction increase or diminish the inherent attractive force of said magnet (receiver)

Bell's instrument proved a striking success (its essential features being embodied in present day receivers) It lacked however the capacity to generate a current of sufficient strength to contend with high resistance lines To overcome this defect the carbon transmitter based on the theory of varying pressure (as explained under Fig 2) was devised by Edison whose ideas are embodied in present day transmitters.

It has been pointed out that a variation of resistance will produce a variation of current That this is the general principle underlying the transmission of speech may now be thoroughly appreciated by re-reading the text pertaining to Fig 2

A general assembly circuit embodying all the necessary features of an elementary telephone system is shown in Fig 5 Here if M wishes to talk to N the crank of the generator G is turned (switch hook H

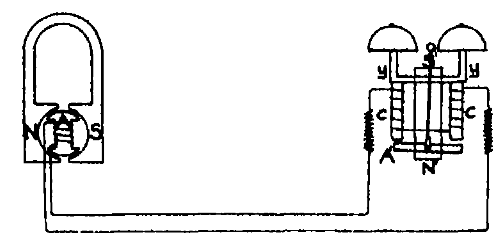

Fig 3

down) ringing current passes out on the line through switch hook H to the bell B and back to its source (G) by way of the shunt (Fig 4) attached to G B and B ring at the same time M now takes his receiver off the hook and waits for N to answer

If O who is in the immediate vicinity wishes to establish telephone communication with both M and N an instrument is placed on his premises with separate pairs of wires going to the respective instruments of M N and O When there are more than two or three instruments some form of sliding contact lever key is also provided at each instrument for placing any two stations in circuit. Fig 6 indicates the form such lever key arrangements may take With the key in its normal position M is always in circuit with every station in the system If M wishes to call say L the key must first be moved to the position indicated by the broken line Contact is thus broken at n o l and q and M is in circuit with L only

It is along lines similar to the above that what is known as an Intercommunicating System is established Such systems in a variety of forms are in common use in offices factories hotels etc where the number of stations does not exceed say twenty five A greater number than this necessitates such an amount of wiring and complication of circuits as to make the system both expensive and cumbersome

IV

Considerations of a technical commercial and practical nature have made the Central Station method the only successful one for handling a large number of telephone stations Here every telephone station has but two wires which terminate in a central office where an operator is provided with suitable devices for placing any two stations in circuit

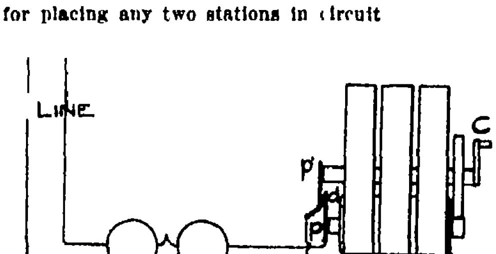

Fig 4

Central offices may be divided into three general classes

1 Automatic
2 Magneto
3 Common Battery

Automatic central offices aim to do away either entirely or in part with the services of operators Here, the central office equipment is very complicated and does not permit of sufficient flexibility At the present time there are comparatively few automatic systems in operation

Magneto central offices are not subject to the above objections, but here the subscriber's equipment (which is as indicated under Fig 5) entails an outlay of dead capital (local battery and generator), the maintenance cost per instrument is excessive (battery needs frequent attention), and the subscriber is

required to perform duties which are burdensome and inconvenient (holding switch hook down and operating hand generator to "ring" central) Magneto systems are being rapidly replaced by common battery systems, which though by no means perfect, yet possess those elements which stand for convenience electrical efficiency reliability, economy and flexibility

The basic elements of a common battery system are shown in Fig 7 The subscriber's equipment consists of a transmitter receiver induction coil (not shown) switch hook polarized bell and condenser The subscriber's pair of wires terminate at the central office switch board in what is termed an answering jack The subscriber's lamp with its battery is connected to the answering jack springs as shown Normally the lamp circuit is open on account of the condenser which is a bar to the passage of unvarying currents

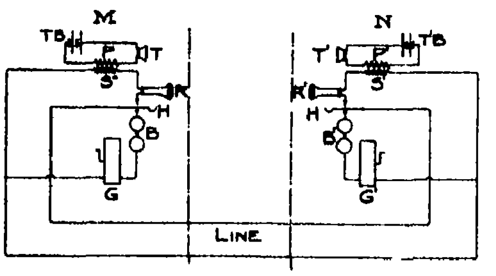

Fig 5

The common battery or talking battery is wired in multiple between the answering and calling cords Each pole of the battery is connected to these cords through a divided repeating coil one limb of each cord being connected to one of the four windings of the repeating coil The operation of a transmitter in circuit with either cord will produce a varying current which will act inductively through the repeating coils upon the other cord

Thus if A wishes to speak to B he takes the received off the hook and unconsciously makes contact at d which lights his central office lamp On seeing the light the central office operator inserts the plug of the answering cord into A's jack and puts her telephone instrument in circuit with A by pressing the talking key (As an incident to the insertion of a cord plug into a jack the jack springs are pressed away from the lamp circuit contacts thus putting the lamp out) When A tells the operator that he wants B she inserts the plug of the calling cord into B's jack and presses the ringing key This sends alternating current out on the line through the condenser (which is no bar to alternating current) and the bell When B takes his receiver off the hook communication between A and B is established

When B is transmitting the windings $c\,c$ will operate as the primary windings of a transformer of which the secondary is formed by cc The variation of current produced by B's transmitter will act inductively through the repeating coils and produce a corresponding variation of current in A's circuit thus actuating his receiver

V

There are few industries in the United States which have made more rapid progress than that of telephony. The first successful telephone instrument was introduced by Prof Bell in 1876 Early in 1877 the manufacture of telephone instruments took definite form and by the end of the year there were about 60 000 instruments in use This enormous progress (although the percentage rate of increase has been greatest in the past few years) has been continuous

The report for 1907 shows that the Bell system has about four million subscribers and that the actual value of Bell plants and working capital is $589 000 000 Gross earnings for the year amounted to $120 000 000 The number of local messages averages eighteen million daily the number of long distance messages nearly a half million daily

The above figures would perhaps be enlarged once over if reports from all the independent companies were available

The figures would tend to indicate that with the great capital invested the number of persons employed must be enormous and that therefore telephony as a field of effort must rank among the leaders

---

The California ground squirrel is costing the country millions of dollars because of its destruction of grain, fruits and nuts and its tunneling in irrigation embankments. In May, 1910 it caused a break in the Turlock Canal in Stanislaus County which cost $25,000 to repair, in addition to the loss of the use of the water, estimated at over half a million dollars Still more important is the fact that the ground squirrel has become plague-stricken and unless vigorous measures are used for its destruction the disease may become endemic as it is in India among certain of the native rodents There is danger that the disease may be communicated to human beings and spread to other States The most effective means of destroying the ground squirrels has been found to be whole barley coated with a starch solution holding strychnine in suspension With this preparation the squirrels may be practically exterminated over large areas at a cost of from 3½ to 6 cents an acre depending on their abundance This preparation may be safely employed in pastures on sheep ranges and along public highways The poison should be administered before the breeding season

The Corrosion of Iron

We have no intention of troubling our readers by jejune remarks on the importance of the matter on which we indite The point of interest for engineers is the cause of the corrosion which destroys their structures for the reason that the cause being found remedies may be provided

Hitherto there have been two rival schools with their respective scholars and an academy with a scholiast at its head which and who are now dismissed The schools are known as the carbonic acid and the electrolytic schools and put briefly their doctrines are these The carbonic acid exponents believe that the rusting of iron is conditioned by the interaction between the metal and the oxygen of carbonic acid which in the presence of water forms ferrous carbonate this being decomposed by further oxygen to form ferric hydroxide and to liberate carbonic acid which is the evil emissary laying the iron open to attack The upholders of the electrolytic theory maintain that the intervention of carbonic acid is an accident and unnecessary as a mode of explanation They hold that pure iron has in itself a solution tension—in plain words a tendency to dissolve—in pure water just enough to cause it to displace the hydrogen of that water to form a solution of ferrous hydroxide and to produce rust when this solution is exposed to oxygen—from air it may be Experiments are given by both protagonists diametrically opposed The believer in the electrolytic theory states categorically that he has been able to dissolve pure iron in pure water his opponent shows with great exactitude that pure iron is unattacked by pure water even in the presence of oxygen but on the incursion of the merest trifle of carbonic acid corrosion occurs and proceeds Honest thanks are due to both these honest workers and from the conflict of their opinion something useful may be picked

It is a fundamental fact that in a system composed of the pure substances iron water and oxygen the oxidation of the iron should take place because the energy of the system is thereby degraded It is also known that to upset the equilibrium of such a system which may be unstable some *quantum*

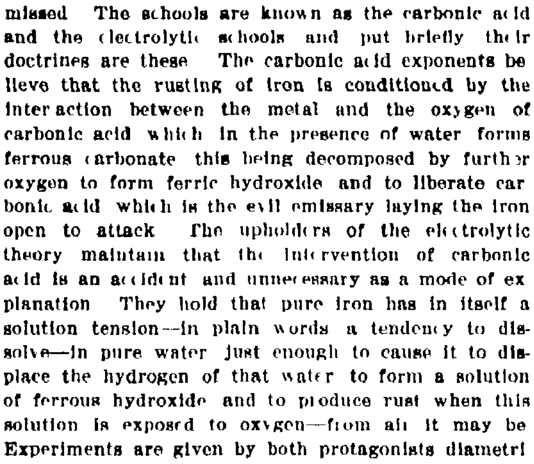

Fig 6

quid may be needed This in the present instance may be termed an electrolyte Water when as pure as the chemist can secure is so nearly a non-electrolyte that its influence may be dismissed But any ordinary water condenser water and still more the natural water which in practice commonly comes into contact with iron contains abundance of electrolytes Pure iron is no doubt, homogeneous in the fullest sense but no one who has looked at the polished surface of a piece of commercial iron—and *a fortiori* steel—under the microscope would hesitate to pronounce it miscellaneous in texture As neither pure iron nor pure water ever come together in practice it may be pretty safely assumed that these two materials in the presence of oxygen will suffer ordinary corrosion and in this respect the electrolytic advocates are right although their experiments were designed to avoid such *contretemps* as commercial iron and common water *Per contra*, the carbonic acid dialecticians have proved their point almost to the hilt by working with precautions bearing the most remote relation to those obtaining in a boiler When the sides are balanced and when all proper allowance is made for the serious difficulties of experiment—difficulties which can scarcely be appreciated by any who has not himself encountered them—the matter according to our present knowledge may be summed up thus

Commercial iron including all forms of steel, is a heterogeneous body Ordinary water contains a variety of salts which are electrolytes In the presence of oxygen the iron will be oxidized as thermochemical considerations require The rate of oxidation will depend jointly on the degree of heterogeneity of the iron and on the amount and completeness of dissociation of the electrolytes But as in every natural water carbonic acid exists and as it can act as

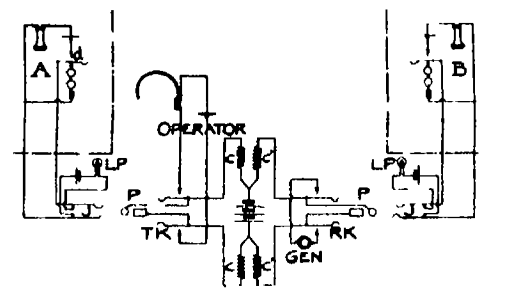

Fig 7

a labile acid uniting with ferrous hydroxide and being expelled from that combination by oxygen (ferric hydroxide being formed) again to take up its role as a constituent of ferrous carbonate it is pre-eminently fitted to serve as a destroyer Iron in the ferric state is sufficiently basic to hold most other acids but carbonic acid it cannot hold and thus it turns the emissary back to do further mischief In practice both causes of destruction are at work the heterogeneity of the iron and the liability of the carbonic acid—the presence of an electrolyte being understood

Formulation of our present knowledge and description of its foundation is easy but what about the remedy? It is best to say at once that none exists As long as the heat of combination of iron with oxygen remains at 68 000 cal and as long as these two elements are in contact with one another so long will iron rust provided a few necessary conditions occur and these are so ordinary that their existence may be assumed In special cases it is possible to prevent the corrosion of iron by making it passive or by making it electronegative but these are rare enough to be put as instances and not as examples In most cases the engineer has already decided that the provision of a skin which shall block the passage of oxygen to the iron is the best mode but as his idea of a skin usually resolves itself into one of paint the outcome is generally poor Certainly it may be improved by the use of more rational preservatives than paint such as tar applied as hot as it can be got upon the structure But this is scarcely a help in protecting the inside of a boiler and if it be admitted as it must be admitted if any fragment of our knowledge is right that the destruction of a clean unprotected boiler of any sort fed with clean ordinary water is certain then thankfulness may be felt that clean ordinary water commonly provides its own protection for the boiler in the homely form of scale

There is no royal road Iron is won by the expenditure of fuel and is potentially a combustible Wherever it meets oxygen it will endeavor to unite with it The rate of union is neither here nor there the tension making for union remains As that tension is elemental and invincible the only means for its frustration is a severance of the two bodies by an impermeable septum and as our friends the electrochemists have given us such valuable help in this matter we crave their aid for its provision

Gypsum	6				1	8
Cornish stone	50	20	20		7	
Bone ash				2[illegible]		

Add coloring metal oxides Blue 0 , oxide of cobalt dark green 1 part chromic oxide blue green 0 3 chromic oxide and 0 3 cobalt oxide light green oxide of nickel bluish green oxide of copper yellow antimony yellow brown in place of flux add to the plastic clay about 0 33 of calcined ochre (iron dross) and about 8 parts of manganese

What Electrochemistry is Accomplishing—II*

Modern Methods and their Results

By Joseph W Richards

Concluded from Supplement No 1830, page 51

III Electric Furnaces

Electric furnaces are furnaces in which the necessary heat or degree of temperature is produced or attained by means of electrical energy The electric current is used in these furnaces solely for its heating or thermal effect and either alternating or direct current may be used but alternating is preferred because of its easier generation and management capability of being procured from transformers and absence of electrolytic effects

Electric furnaces render remarkable and highly valuable service to the chemist and metallurgist for two distinct and unique capabilities they can generate heat within themselves without the use of combustion and the consequent products of combustion to complicate the working of the furnace and they can besides if desirable produce temperatures absolutely unapproachable in furnaces using fuel and thereby enable the carrying out of operations only possible at these extremely high temperatures The upper limit of electric furnace temperature is simply the volatilizing point of carbon the temperature at which the material of which the lining of the furnace is made is boiled away This is about 3 700 deg C or 6 692 deg F The simple statement that this is three times as high as the melting point of cast iron may give some notion of the enormous temperature here at one s command Besides high temperature the efficiency of application of electrical heat to the useful purpose is usually high in many cases 60 to 75 per cent of all the heat developed can be usefully applied as against 5 to 50 per cent utilized in fuel fired furnaces The heating value or thermal equivalent of the electric current is perfectly definitely known one kilowatt hour will furnish 860 calories (3 400 B t u) which if applied usefully at 100 per cent efficiency would bring to boiling and convert into steam 1 35 kilogrammes (3 pounds) of water or bring to melting and melt about 3 kilogrammes (6 6 pounds) of cast iron or 2 5 kilogrammes (5 5 pounds) of steel

Artificial graphite is a product particularly electrochemical in its manufacture Your fellow townsman Dr E G Acheson has practically created this industry and his name sticks to the product—Acheson graphite No temperature but that of the electric furnace can convert the ordinary amorphous carbon containing small amounts of foreign substances into pure soft, homogeneous unctuous graphite The purity of the product and its quality has even surpassed the artifice of Mother Nature herself Whereas before graphite in small scales was laboriously gathered from Ceylon and Siberia and with great pains worked up into graphite articles now the articles are simply molded in ordinary impure amorphous carbon and converted through and through retaining their shape into finished and complete graphite articles What this highly pure product is going to do for lubrication for annihilating the friction of the world s machinery perhaps only a few suspect and only Mr Acheson knows You will all know more about this soon and everyone of you who uses machinery will profit by it Meanwhile in another direction probably half the electrochemical industries now operating are beneficiaries of this invention using artificial graphite anodes in electrolytic operations or as electrodes in electric furnaces The electrochemical industry in general has been most wonderfully helped by this one electrochemical process

Carborundum stands for a large industry centered at Niagara Falls and founded also by Mr Acheson Twenty years ago the name was not in the dictionary now it is known all over the world as the most efficient abrasive material in use First produced just across the Monongahela in a little furnace as large as a cigar box and sold for polishing diamonds at many dollars per ounce it is now made by tons in electric furnaces of 2 000 horse power capacity and competes successfully with such common nature abrasives as emery and common sand And in fact common silica sand the most abundant material on earth with common carbon like coke furnish all the ingredients necessary for the furnace to work upon to produce SiC silicon carbide Mr Acheson not merely founded another new industry but he discovered a new chemical compound he has enriched science promoted industry and created new instruments of service no wonder that his scientific friends have showered on him honors—the Rumford Medal the Perkin Medal and two years ago the presidency of this Electrochemical Society

Silicon is the metal whose oxide is silica sand and is by far the most abundant metallic element on earth Up until very recently it was to be seen only in chemical museums costly and useless—a chemical curiosity Now Mr F J Tone one of Mr Acheson s former lieutenants is producing it by the ton and selling it by the carload at a few cents per pound The chemical world has found uses for it, large uses such as in solidifying steel making good copper castings reducing other metals from their oxides chemical pots and pans etc This illustrates again the variety of the achievements of electrochemistry Here is a new material furnished the world at a low price and all sorts of workers are finding all sorts of advantageous uses for it The electric furnace makes it from simply sand and carbon with electric energy, and plus considerable brains.

Calcium carbide is the product of another American invention The name was scarcely in chemical books and the purveyors of the rarest chemicals did not have it on their lists when Mr Thomas Wilson trying to make something else in the electric furnace made this compound from ordinary lime and carbon and started an electrochemical industry which has spread all over the civilized world I am almost tempted to say that there is a calcium carbide works everywhere but in Pittsburg but that would really be an exaggeration and I will not say it. The best thing about calcium carbide is that it is easy to make the raw materials may be found almost everywhere and wherever power is cheap a flourishing calcium carbide industry may be built up The curious thing about it is that its chief use is based on destroying it acting upon it by water and forming acetylene gas How great a boon acetylene gas has been to the bicyclist automobilist for lighting trains isolated houses stations and towns needs no recital before this audience but the value of acetylene as a means of welding with the blowpipe is only commencing to be appreciated Acetylene welding is a convenience which owes its existence entirely to the electrochemical production of calcium carbide and the iron and steel and other metal industries are being greatly helped by its use

Titanium carbide is not as familiar as calcium carbide It is made in a manner similar to the production of carborundum using titanium oxide (rutile) and carbon It has no uses similar to calcium carbide nor any like silicon carbide But electrical engineers have discovered that as arc light tips or electrodes it gives the most efficient arc light yet discovered with a light efficiency running up to 3 candle-power per watt of electrical energy This is probably 50 per cent of the theoretically possible conversion of electrical energy into light energy and is doubly as efficient as has ever before been attained What this means for street lighting everywhere is difficult to realize perhaps the best and most easily understood comparison is to say that the titanium carbide arc lamp is to the ordinary arc as the tungsten filament incandescent lamp is to the carbon filament lamp you will all grasp the scope of that statement. With acetylene lighting on one hand and titanium arc lighting on the other we need say no more about the influence of electrochemistry on modern illumination

Phosphorus I stated before that the potassium chlorate on safety matches was all being made electrochemically We can say practically the same of phosphorus The electric furnace enables us to distill phosphorus much more easily and safely from the natural phosphates than the older chemical methods Calcium carbide gives us acetylene gas and another electrochemical furnace gives us the phosphorus to strike the light."

Ferro-alloys are alloys of iron with the more expensive metals used in manufacturing steels of various kinds Ferro-manganese is used in practically all steel ferro-silicon is used in almost all Ferro-chromium nickel tungsten molybdenum boron, uranium, vanadium are some of the alloys used to make the special alloy steels such as find great use in rapid tool steel automobile axles armor plate, gun steel, etc These alloys are of great importance to the steel industry and are made almost exclusively in electric furnaces The industry has flourished most in countries having cheap power, such as among the French Alps and the importations into this country have been on a large scale Fortunately, we are commencing at Niagara Falls, in Virginia, and in Canada, to supply ourselves with these necessities of the steel industry, and we may look forward to a steady and large domestic development of this industry Within a few miles of this hall a small electric furnace is now at work making ferro-tungsten to go into high-class expensive steel Pittsburg is going to take its share in the running of this particular electro-metallurgical industry

Pig iron would seem to be about the last item to find a place in an address upon the electrochemical industries But the truth must out electric furnace pig iron is now being made and made and sold at a profit We will hasten to admit that the furnaces are small that they are in California and Sweden, where fuel is expensive and power is cheap that a great deal of money has been sunk in bringing them to their present condition but after all has been admitted the fact remains that electric furnace production of pig iron is not a chimera but an accomplished fact. Pittsburg has been able to boast that she "could manufacture a ton of pig iron and put it down anywhere in the world cheaper than it could be there produced That may be *still* true *of the kind* of pig iron which Pittsburg is able to make but there are grades and qualities of pig iron (Swedish charcoal pig iron, for instance) which are still imported into this country and sold at double the price of our domestic pig iron And in the country where that charcoal pig is slowly laboriously and skillfully made the electric shaft furnace is able to compete with the charcoal blast furnace in producing this high quality pig iron Dr Haanel of the Canadian Department of Mines has in a recent report given us the most reliable information about the running of this furnace The construction is peculiar and still somewhat experimental the full power for which the furnace was designed has not yet been available for running it the workmen are new to their tasks the overseers are still learning the irregularities in the running are not yet all overcome and many of the minor details are yet being adjusted The furnace is still in brief decidedly in the formative or experimental stage Yet notwithstanding Prof Odelstjerna one of the most expert of Swedish metallurgists states that the cost of production is $1 50 per ton less than in the Swedish blast furnaces If that is true now it needs little gift of prophecy to figure out at least $2 50 per ton saving when the furnace is properly run Three similar furnaces of greater capacity 2 500 kilowatts each are to be erected in Norway three similar ones are to be put up at Sault Ste Marie Canada. These are only the forerunners we may be sure of dozens or perhaps even hundreds which will be built and operated within the lifetime of most of this audience The time at our disposal forbids me describing these interesting furnaces I can only refer you to Dr Haanel s interesting reports and to the transactions of this society, particularly our volume xv One surmise of my own I will however take time to mention I have predicted that this electric furnace pig iron made without the admittance or use of air blast will be far superior to ordinary pig iron for conversion into steel because of the absence of oxygen or particularly, of nitrogen. *Time* will test this prediction too

Electric steel is at present a topic of absorbing interest and great potentialities It was primarily a competitor of the most expensive kind of steel—crucible steel It was first made commercially in 1900 by Mr F A. Kjellin of Sweden by melting together in an electric furnace the same high-grade materials which are usually melted down in crucibles to form crucible steel The product was made equal in quality to crucible steel It was produced in lots of a ton or more at a melt of very satisfactory uniformity and with cheap water power to furnish electricity the cost was considerably below that of crucible steel

The steel melting pot or crucible is a siliceous vessel holding about 100 pounds of steel, lasting only a few heats, and lifted in and out of the furnace by manual labor The consumption of fuel to get the required melting heat is wickedly wasteful, not over five per cent of the heat-developing power of the fuel used is efficiently utilized as heat in the melted steel, and the actual proportion is usually less than half that much The cost of labor crucibles and fuel is excessive, and to this must be added the high cost of the pure material which must be used—practically the purest iron which can be made.

The electric furnace is changing all this, rapidly in continental Europe, slower in Sheffield, and still

* An address delivered at the Seventeenth General Meeting of the American Electrochemical Society in Pittsburg, Pa and printed in the Transactions of the Society

slower in America, but the change is spreading surely and inevitably Real crucible steel will soon be a thing of the past supplanted entirely by electric furnace steel of equal quality made and sold much more cheaply

The electric furnaces used are of almost all types The induction furnace was developed commercially by Kjellin in Sweden improved enlarged and greatly developed by his associates in Germany combined with the Colby pattern in America, and still further modified by Hiorth in Norway Thirty-six of these furnaces, the maximum capacity being one at Krupp s works at Essen 8½ tons at a charge are now built or building The American Electric Furnace Company is organized to push their building and operation in America The arc radiation furnace was developed by Major Stassano an Italian artillery officer It melts by heat radiated from powerful electric arcs Several of these are in operation in Europe and a gentleman managing one of the large American steel companies who has just returned from an inspection of the different electric steel furnaces operating in Europe tells me that he considered the Stassano furnace as doing the best work all around of all the furnaces he saw in operation I have seen this furnace operating smoothly and regularly in Turin producing steel for castings which were being sold in competition with open hearth and Bessemer steel castings in the open market The single arc furnace is best illustrated by the Girod furnace which is built like the body of an open hearth furnace with the electric current entering the bath by carbon electrodes suspended above it and springing arcs to it while the current leaves the bath through metallic conductors passing through the saucer shaped hearth below the level of the metallic surface These furnaces work with great regularity and a large number are operating in Europe in capacities up to 12 tons each I am informed that the Krupp works at Essen has just contracted to put in five of these of the 12 ton size which would confirm statements made to me by my European friends that this furnace is working the best of all the electric steel furnaces now operating in Europe The double arc furnace of which the Heroult furnace is the most familiar type works with two arcs in series the current entering the bath and leaving it also through electrodes suspended above it The general style is that of an open hearth furnace with electrodes passing through the roof The current used is roughly 100 kilowatts per ton of steel capacity and the largest so far operated is 15 tons A three-ton furnace of this type was seen by you at the Firth Stirling Steel Works at Demmler yesterday producing crucible-quality steel The U S Steel Corporation has acquired licenses to operate the Heroult furnace and has already two 15 ton furnaces in operation Without doubt, the Heroult furnace is at the present time the most popular and successful electric steel furnace in the United States I have not time to more than name the Keller the Hiorth the Harmet the Frick—all of which are operating at this present moment in Europe

There are other ways of making steel than the crucible method Bessemer steel is the cheapest and open hearth steel is next best These two varieties grade into each other in quality but between open hearth and crucible steel there is an enormous gap in price and in quality which is destined to be bridged over by intermediate qualities of electric steel as it becomes cheaper and is manufactured on a larger scale This will soon become one of the large uses of the electric method occupying a field peculiarly its own It will enable steel manufacturers to supply steel better than the best open hearth product at less than the price of crucible steel I need not enlarge upon the advantages of this to a Pittsburg audience

There are also varieties of methods of manufacture of steel aside from the melting together of highly pure materials as in the crucible method which are equally available in most types of the electric furnace The Bessemer converter takes liquid pig iron as it comes from the blast furnace and by rapid oxidation by air blast converts it into steel Mr Heroult has tried to combine the Bessemer converter with the electric furnace in one apparatus the idea being to first oxidize the metal by air blast and then to finish it while electric current supplied the necessary heat I have no information that this combination furnace is anywhere in successful operation but the equivalent of the same operation performed first in the Bessemer converter and then on the blown metal transferred into an electric furnace for finishing is already in regular commercial operation at the South Chicago Works of the U S Steel Corporation I have had the privilege and pleasure thanks to Mr Heroult of studying that operation in company with Mr Heroult and the editor of Metallurgical and Chemical Engineering You may find a description of the process in the April number of that journal so I will not repeat it here—except so far as to say that 15 tons of the product of the Bessemer blow oxidized to the extent usual in the Bessemer converter was kept melted less than two hours on the basic hearth of the electric furnace treated with two different slags to refine it from phosphorus and sulphur deoxidized or dead melted and then poured into ingots of steel intended for axles The steel produced was of better quality than the usual corresponding open hearth metal and was produced at slightly less total cost This combination process bids fair to give a new lease of life to the declining Bessemer steel industry its economic importance is evident

The open hearth steel furnace is at present the most important of the methods of manufacturing steel—"tonnage steel It makes steel from pig iron and scrap of proper quality or from pig iron and iron ore (mill-scale) or from pig scrap and ore It makes its best steel on silica hearths from high grade material low in sulphur and phosphorus and its cheapest steel on basic hearths from almost anything The electric furnace can do any or all of these things and as a general proposition produce better steel from given materials than the open hearth furnace Under what circumstances it will pay to use the electric furnace instead of the open hearth furnace would take at least one lecture to discuss we will not go deeply into it here In Europe countries which have very cheap water power around $10 per horse-power year and fuel costing $4 to $6 per ton are finding the electric furnace the cheaper with power costing $20 and coal $5 the two are about on equal terms in Pittsburg with power at $30 and coal at $1 the open hearth furnace is by far the cheaper for producing such steel as it can produce However even here the combination of Bessemer and electric furnace is possibly cheaper than the all open hearth process the combination of open hearth and electric furnace process is quite possible and practicable to produce crucible quality steel on a large (tonnage) scale and the combination of the open hearth and electric furnace into one furnace is not only a possible combination but is actually being tried out

The latter idea is to take an open hearth furnace and to place electrodes in the roof The furnace is run as an ordinary open hearth furnace with the electrodes withdrawn and at the close of the open hearth heat gas and air are shut off entirely the electrodes lowered into proximity to the bath and the heat finished as an electric furnace heat The idea is sound and practicable and will result in the production of better steel than can be obtained from any open hearth furnace at but a slight advance on the cost of the open hearth steel say $2 to $3 per ton

As to the capacity for enlargement of electric steel furnaces they started out to duplicate the crucible steel process producing 100 pounds of melted steel at a heat and in eight years have risen to 15 tons capacity In Europe an electric calcium carbide furnace of 18 000 kilowatts capable of producing 200 tons of carbide daily is in practical operation A furnace of like power capacity could be built to make steel and would be a 200 ton steel furnace or larger We can therefore say with assurance that with a little more experience and experiment electrometallurgists will be able to furnish the steel maker with electric steel furnaces as large as are wanted—up to 200 tons capacity if desired

Polonium

POLONIUM was the first of the active substances separated from pitchblende residues by Mme Curie Various methods of concentration were devised by her with the result that preparations of polonium mixed with bismuth were early obtained many thousand times more active than uranium Marckwald later separated from 15 tons of pitchblende about 3 milligrammes of intensely active material which he called radio-tellurium since it was separated initially with tellurium as an impurity By dipping a copper plate into a solution of this substance he obtained a deposit of weight not more than 1/100 milligramme which was far more active than an equal weight of radium It was soon recognized that this preparation was identical with polonium for it gave off the typical α radiation and had the characteristic rate of decay of that substance Unfortunately Marckwald was not aware at the time of separation of the great importance of testing whether lead appeared as a product of transformation of polonium Before such an experiment could be made the polonium to a large extent had been transformed

Polonium is one of the numerous transition elements produced during the transformation of the uranium radium series It is half transformed in about 140 days emitting α particles during the process Rutherford showed in 1904 that polonium was in reality a transformation product of radium itself Radium at first changes into the emanation and then successively into radium A B C D E F radium F being identical in all respects with the polonium directly separated from a radio active mineral When the radium emanation is allowed to decay in a sealed glass tube, the walls of the tube are coated with an invisible deposit of pure radium D radium E and radium F, but the amount of the latter to be obtained in this way is far too small to be weighable

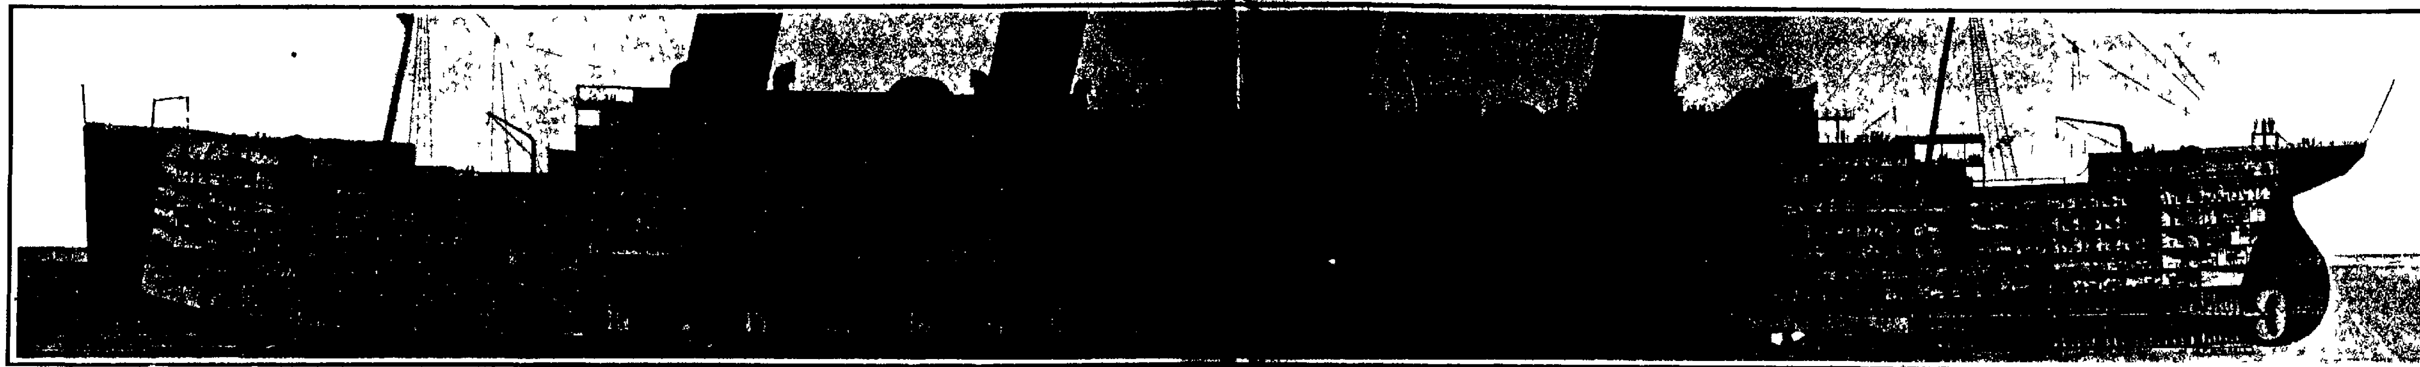
The amount of polonium present in any radio-active mineral can easily be calculated Since the radium and polonium (radium F) in a mineral are in radio-active equilibrium, the same number of α particles are expelled from each per second Since polonium is half transformed in 140 days and radium in 2 000 years the former breaks up 5 000 times faster than the latter The maximum amount of polonium to be obtained from a mineral is in consequence only 1/5 000 of the amount of radium In 1 000 kilogrammes of pitchblende containing 60 per cent of uranium there are present 170 milligrammes of radium The weight of polonium is about 1/5 000 of this or about 1/30 milligramme It is thus obvious that to obtain 1/10 of a milligramme of pure polonium several tons of high grade pitchblende must be worked up The most natural source of polonium is radium D (radio-lead) which grows polonium and has a period of half transformation of about twenty years Since polonium breaks up about 5 000 times faster than radium its activity weight for weight should be about 5 000 times greater than that of radium There is nothing surprising in this for the radium emanation has an activity about 200 000 times that of radium while radium A (period three minutes) must have an activity 400 million times that of radium itself Since the radiation from polonium is entirely in the form of α rays it is to be expected that the radiation from it would show chemical and physical effects identical with those observed for pure emanation the only difference being that the products of the latter emit β and γ rays as well

Apart from the interest of obtaining a weighable quantity of polonium in a pure state the real importance of the present investigations of Mme Curie lies in the probable solution of the question of the nature of the substance into which the polonium is transformed This problem has been much discussed in recent years Since polonium emits α particles one of its products of decomposition as for all the other α ray products should be helium The production of helium from a preparation of polonium has been observed by Rutherford and Boltwood (Manchester Lit and Phil Society November 30th 1909) and also by Mme Curie and Debierne in their present experiments Boltwood several years ago suggested that the end product of the radium series was lead and has collected strong evidence in support of this view by comparing the amount of helium and lead in old radio-active minerals Since polonium is the last of the active products observed in the radium series it is to be expected that polonium should be transformed into helium and lead one atom of polonium producing one atom of helium and one atom of lead This point of view receives additional weight from consideration of the atomic weight to be expected for the end product of radium Since in the uranium radium series seven α particles each of which is an atom of helium of atomic weight four are successively expelled before radium F is reached the atomic weight of polonium should be $7 \times 4 = 28$ units less than uranium (atomic weight 238 5) This gives an atomic weight of polonium of 210 5 and after the loss of an α particle a final product of atomic weight 206 5—a value very close to the atomic weight of lead

It is a matter of very great interest and importance to settle definitely whether polonium changes into lead The evidence as a whole has long been in favor of that supposition The outlook is very promising that the experiments of Mme Curie and Debierne will settle this question conclusively No doubt an interval must elapse to allow the polonium to decay before the final examination of the residual substance can be made —*Nature*

In a report by the French Consul General at Rotterdam it is stated that 75 vessels of large and medium dimensions aggregating 72 980 tons were built in Dutch yards last year against 76 vessels of 64 806 tons in the year 1908 The average measurement of the vessels built last year was 973 tons whereas in 1908 it was only 850 tons River boats and small seagoing craft were also constructed to the number of 799 and aggregating 150 753 tons the small vessels built in 1908 totaling 683 boats and 112 873 tons A good number of vessels were built for foreign account last year namely—for Germany 60 760 tons for Belgium 9 382 tons for Great Britain 4 2 3 tons for Argentina 3 110 tons for Brazil 1 010 tons other items making up a total altogether on foreign account of 97 900 tons

The World's Greatest Ship—The "Olympic"—a 60,000-ton Vessel



The new White Star liner "Olympic," which was launched from the famous yard of Harland & Wolff at Belfast in October last is far and away the largest vessel ever built, her gross tonnage being half as much again (82 500 tons) as that of the "Mauretania" or the "Lusitania," which until now have held the record for size. Her dimensions are: Length, 882½ feet; beam, 92½ feet; depth (from keel to main deck rail), 62 feet, and her tonnage displacement is 60 000. Her huge hull, divided into thirty water tight compartments, contains nine steel decks, and provides accommodation for 2 500 passengers, besides a crew of 860. She is a triple screw boat and her engines of 45 000 horse power will propel her at a speed of 21 knots. In equipment also she will surpass anything afloat as can be seen from this diagrammatic picture of her interior. The "Titanic," her sister ship, will be launched early this year. Each vessel, when completed, will have cost $7 200 000. —From the Graphic.

THE WORLD'S GREATEST SHIP

The launching of the White Star liner "Olympic" at Belfast on October 20th marked a new advance in naval architecture. Not only is the "Olympic" the largest vessel that has ever been built, but her propelling machinery is of a type that has never been installed on a vessel of such dimensions. After the success of combined turbine and reciprocating machinery in the "Laurentic," it was decided to equip the new steamer with both types of engines and with triple screws.

The "Olympic" outwardly resembles the "Mauretania" of the Cunard Line. She has four elliptical funnels, each 28 feet in diameter. Her length is 888½ feet, her breadth over all 92½ feet, her breadth over boat deck 9? feet, her height from the bottom of her keel to top of her captain's house 10? ½ feet and to the top of the funnels 17? feet; her freeboard is somewhat greater than the "Mauretania's," being about ? feet at the top ? feet to the level of the main deck, ? feet to the boat deck amidships and 42 feet at the stern. She may be distinguished from other four-funnel ships on the high seas by a single pole mast forward of the bridge. The "Olympic" has a maximum draft of 3? ½ feet, on which she displaces about 60 000 tons, as against a displacement of 4? 000 on the same draft for the "Mauretania."

Despite her size, her engines will develop 45 000 horse power, sufficient to maintain the minimum speed of twenty-one knots for which she has been designed. The combined reciprocating and turbine engines are so planned that two reciprocating engines will drive the wing propellers, the exhaust passing into a low pressure turbine driving the center propeller.

The launching weight of the "Olympic," about 27 000 tons, was the heaviest weight ever transferred from land to water, and this operation, always a matter of anxiety to those in charge, was naturally, in the case of so huge a vessel, an undertaking of unusual importance. The method of launching was very simple. The vessel was held on the ways by hydraulic triggers, which were released by the mere opening of a valve, in order that the vast structure might glide into the water.

Some idea of the enormity of the "Olympic" may be obtained when we consider the size and quantity of some of the parts that entered into her construction. Her rudder alone weighs 100 tons, and the weight of the castings comprising the stern frame, rudder and brackets amounts to ?80 tons, or ?0 tons more than those of any other steamer. They were manufactured at Darlington, and special arrangements had to be made for their conveyance to Hartlepool, whence they were shipped to Belfast. The largest beam weighs four tons and measures 92 feet; the longest steel plates are 36 feet. There are 2 500 000 rivets in the ship. Each engine crank shaft weighs 118 tons, each bedplate 19? tons, each column 21 tons, and the heaviest cylinder with its liner 50 tons; the wing propeller 38 tons. The weight of the casting for the turbine cylinder is 167 tons, and of one of the solid bronze propellers 2? tons. The anchors are 19 feet in length and over 1? tons in weight, and each link of their chains weighs several hundredweight. Twelve horses were required to drag one of the anchors to the Naval Exposition at Olympia.

The equipment and furnishings of the vessel have likewise driven home the gigantic size of her hull. Besides the usual dining rooms, lounges, saloons, drawing and smoking rooms, restaurants and verandas and cafés, all beautifully decorated, the "Olympia" will be provided with a complete and well-equipped Turkish bath, a spacious swimming bath, a full-sized squash and racquet court, with a gallery for the use of spectators of the game, electrical bath establishments, sun parlors, sport decks, palm courts, lifts, gymnasiums, etc. These accommodations are provided for 2 500 passengers. The crew will number 860.

Since the advent of the "Great Eastern" in 1858 no vessel except the "Mauretania" and "Lusitania" has created such a vast amount of comment as the "Olympic," not only on account of her enormous size, but also because she represents a new type in naval architecture. In our issue of June 19th, 1909, we published an article on the "Development of the Transatlantic Steamship," in which we traced the evolution of the modern liner from the old "Britannia," which was the first vessel that ever crossed the Atlantic on a regular schedule, to the present day "Olympic." We pointed out at the time that between the "Britannia," with her length of 215 feet and her speed of 8.5 knots, and the "Olympic," with her enormous length of nearly 900 feet and her minimum speed of 21 knots, the changes in construction and in propelling machinery have been remarkable. The two decades that followed the advent of the "Britannia" saw the advent of the "Asia" in 1850, a vessel with a length of 275 feet and a speed of 12.5 knots, and the "Persia," an iron steamship built in 1855, with a length of 385 feet and a speed of 13.8 knots. Then came the "Great Eastern," Brunel's naval masterpiece, a ship so far in advance of her time that she proved a commercial failure, but nevertheless a harbinger of the development which has given us the "Olympic." The "Great Eastern," with a length of 692 feet and a displacement of 28 000 tons, was not exceeded until the "Oceanic" made her appearance in 1899 with a length of 705 feet, a maximum displacement of 32 500 tons, and a speed of 20.7 knots.

The "Great Eastern" marked the transition from the paddle to the screw, for she was equipped with both. The "China," built in 1862, a ship of 3?7 feet in length, with a speed of 14 knots, was propelled by a single screw only. After that the screw propeller completely displaced the paddle wheel. Up to the time of the "City of Paris" and the "City of New York," practically all of the vessels were driven by single screws, a method of propulsion which reached its highest development in the "Umbria" and "Etruria," 525 feet in length and 19.5 knots of speed, with engines of 14 500 horse power. With the "City of Paris" and the "City of New York" began a new period of twin-screw ships driven by triple-expansion engines. When they went into service in 1889, they were by far the finest ships afloat, as well as the largest. They were 560 feet in length, and had a displacement of 16 000 tons.

The "City of Paris" and the "City of New York" were steady and very much along the same lines. The "Lucania," the "Kaiser Wilhelm der Grosse," the "Deutschland," etc., were built in more or less rapid succession, and exceeded their predecessors in size and in speed.

With the building of the "Lusitania" and the "Mauretania," turbine engines permanently entered the field of transatlantic navigation, although the two Cunarders were not by any means the first vessels in which the turbine was installed. In the "Mauretania" and "Lusitania," a speed of from 2? to 26 knots is maintained steadily, but at a cost which might well give less wealthy owners pause. The White Star Line has made no effort to compete with other companies in building ships which will hold transatlantic records for speed. The "Olympic," like her predecessors the "Celtic," "Oceanic" and "Baltic," is a comfortable ship of moderate speed, as speeds go nowadays. In the combination of reciprocating engines and turbines she represents the entrance of a new type whose performances will be watched with not a little interest.

The launching and other exterior views of the "Olympic" were illustrated in the SCIENTIFIC AMERICAN, November 19th, 1910. The present picture is taken from the *London Graphic* and it gives a sectional representation of her interior.

The Structure of Metals

By Dr. Alfred Gradenwitz

One of the most difficult tasks incumbent on the managers of machine shops is the examination of the mechanical and electrical properties of raw materials and the utilization of the results thus obtained for their continued improvement.

In the electrical industry this task, because of the peculiar conditions of the case, becomes especially complicated. In fact, the mechanical properties (hardness, ductility, mechanical strength, etc.) being anything but parallel to the electrical properties (insulation, conductivity), two opposite tendencies have to be accounted for. This industry therefore is especially interested in availing itself of the most perfect processes of chemical and of mechanical analysis.

Whereas the chemical composition of a given material can always be ascertained by means of a more or less complicated analysis, the thermal processes (melting and annealing) and the mechanical operations (rolling, compression, drawing, etc.) undergone by the material cannot be checked by the old methods with all the accuracy and safety required. The metallographic methods recently suggested are therefore specially useful in this case.

The Cable Works of the A. E. G. of Berlin has been among the first to adopt this method. The following examples, two of which are illustrated herewith by microphotographs for which we are indebted to the courtesy of the directors of the works, will give a striking idea of the many advantages afforded by a microscopic examination of polished cross-sections.

The first example is a microphotographic picture representing a brand of cast copper as obtained from wire refuse in the refining furnace. The copper (Cu) having absorbed in melting large amounts of oxygen (O), has united with this element in the shape of red oxide of copper (Cu_2O) incorporated with the copper under the shape of a fine powder up to a certain density corresponding to saturation. By an examination of the microscopic cross-section, the crystals of pure copper (1) are seen suspended in a saturated solution (2) of copper-red oxide of copper.

In the second example, Fig. 1 represents a microphotographic picture of cast copper in which the percentage of red oxide has been increased by intense superheating. Wherever the limit of saturation was exceeded, the red oxide has separated from the solution as well-defined crystal. The following three components of the metal structure are therefore observed in the microscope: Pure copper (1), *copper-red oxide* solution (2), pure red oxide of copper (3).

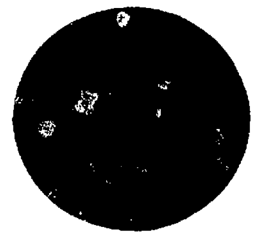


FIG. 1.—A MICROPHOTOGRAPHIC PICTURE OF CAST COPPER SUPERHEATED INTENSELY
Magnified 100 times

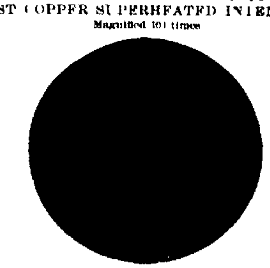

FIG. 2.—STRUCTURE OF SAME SPECIMEN WHEN NON-MAGNETIC

In Fig. 2 is shown the microphotographic picture of a roughly purified cast copper, where the oxygen has been accumulated with a view to burn any metallic and non-metallic impurities, as well as to prepare a reduction as violent as possible of the oxygen, forcing any foreign substances burnt or otherwise to the surface of the bath by a purely mechanical process. As soon as this reduction has been affected the picture (as seen from Fig. 2) only comprises some thin threads of red oxide (2) and copper crystals (1).

Another example finally represents a perfectly refined cast copper. As the red oxide even in slight quantities is detrimental to the mechanical and electrical properties of copper, the oxygen having once done its duty should be driven out completely. The cast copper therefore is submitted once more to intense heating and to reduction, after which even the most minute metallographic observation will no longer ascertain any traces of oxide. Reduction is effected by the immersion of a birch trunk, the components of which (carbon and hydrogen) possess so strong an affinity for oxygen that this element, suddenly leaving the copper in great amounts, combines with the reductive elements, while the melt undergoes a violent seething.

Similar sets of metallographic pictures are prepared at the Cable Works of the A. E. G. for any operation of some importance, three chemists being intrusted with the checking of materials by comparing these pictures with those of typical standard.

After having enriched to a surprising extent our knowledge of living organisms, the microscope thus promises to render an equally efficient assistance to the engineer engaged in industrial pursuits.

The City Water Sterilizing Process Used at Marseilles

By the Paris Correspondent of the SCIENTIFIC AMERICAN

THE fact that city water can be sterilized on a large scale by the use of ultra-violet rays has been well brought out in a series of tests which were made at Marseilles not long since. Owing to the knowledge that the Durance River contains a large amount of bacteria, the municipality felt the need of providing a suitable method for sterilizing the water and one which should allow of a large delivery at the same time. The results of the tests seem to show that the ultra-violet ray method is by far the best for sterilizing and is at the same time easy to carry out with a rapid delivery and takes but a small amount of current, hence the cost is low. We wish to describe the new apparatus for city water use which is designed by Messrs. Henri Helbronner and de Recklinghausen, and it is gratifying to observe that the experiments carried out by V. Henri at the Paris University are now taking a practical shape. There seems to be a great future in store for the new method, seeing that it has none of the drawbacks which are found with the other processes when it comes to using it on a large scale.

In the sand filtering method, for instance, the filters occupy a large surface of the plant, and when not properly operated the results are very imperfect. Besides, the first cost of installing the filtering plant is high. Chemical products added to the water for sterilizing have the disadvantage of giving a bad taste to the water, and the method is not much favored for that reason. One of the best methods for municipal plants has been the ozone process, and it has been used in some large cities. However it gives a certain taste to the water which disappears but slowly, and on the other hand there must be great care taken in the ozone production in order to avoid forming any nitrogenous products which would vitiate the water. Hence the process is somewhat difficult to carry out, or at least needs great care and attention.

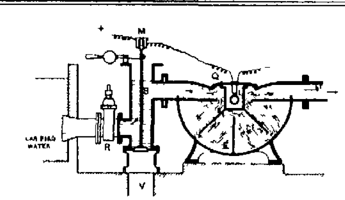

FIG. 2.—SECTIONAL VIEW OF APPARATUS FOR STERILIZING CITY WATER

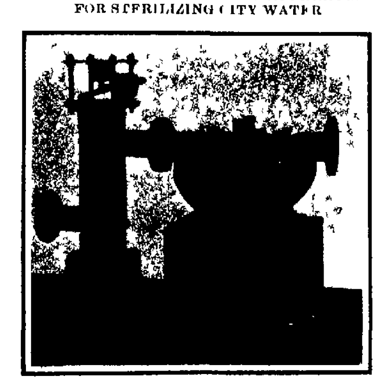

FIG. 1.—APPARATUS USED FOR STERILIZING CITY WATER BY EMPLOYING ULTRA-VIOLET RAYS

In order to find the best solution of the problem the municipal council of Marseilles organized a concourse of sterilizing apparatus. Such a plant was required to deliver 200 cubic meters (261.5 cubic yards) of water per 24 hours and was to be run continuously for one month. The inspection committee included some of the leading specialists in hygiene, mining and civil engineers, and professors of universities. The results of the tests showed that the ultra-violet ray process was undoubtedly the best for municipal use, as it has none of the defects which we mentioned above. It uses a small amount of current, and this has now been lowered in the new apparatus. Neither taste nor smell is given to the water, and the sterilizing is very effective. At the same time the process is easy to carry out and the apparatus needs but little attention. The first cost of the plant is low, and it occupies but a small space.

The ultra-violet ray apparatus was used in connection with a Puech-Chabal filter in order to act upon clear water, and this was necessary from the fact that the Durance water is very heavily charged with impurities which render it turbid. After leaving the filter it passes at a continuous rate through the ultra-violet ray apparatus.

Fig. 1 of our engravings shows the appearance of the Marseilles apparatus and Fig. 2 the sectional view. In the former apparatus the lamps were placed above the surface of the water upon floats so that all of the radiation from the lamp could not be used, and in fact there was only one-third of the rays actually employed for the sterilizing. The authors sought for a means of utilizing a greater proportion

of the rays without changing the manner of working the arc It is recognized that the working of the lamp depends essentially upon the temperature of the electrodes and the luminous tube so that if we cool the lamp too much we will not obtain the same yield in ultra violet rays as before and to reach the same yield the current must be considerably increased For instance if we immerse the quartz lamp in the water itself according to Messrs Courmont and Nogier s method we are obliged to double the current in order to obtain the same yield as in air

A great improvement is obtained by the present apparatus in this respect as it allows of utilizing more than three-quarters of the rays given by the lamp and here the lamp burns in air at its best conditions of working and we thus avoid immersing it in the water The lamp is placed in a rectangular case whose three sides lying parallel to the lamp tube are formed of quartz plate The tight box Q containing the lamp L is placed in a semi-circular apparatus having five partitions in the inside The water is taken from a tank of filtered water and passes through a gate valve and a cylinder chamber S then entering the main tank E It follows around the path which the arrows indicate and in this way it is exposed for some time to the action of the ultra-violet rays, so that we have a powerful sterilizing effect. It is found best in practice to use an automatic valve at the water inlet and it operates in the chamber S A valve in the lower part of the chamber is normally closed and is held up in this position by an electromagnet M which attracts an armature mounted on the end of the valve rod A counterweight is used to give the proper adjustment of the weight. The electromagnet is connected in series with the lamp so that when current passes in the lamp circuit the magnet acts and the valve is held closed. Should the current fail or the lamp break the magnet allows the valve to drop and the water now passes directly out of the apparatus by V into the sewer or elsewhere and no water will be delivered into the sterilizing chamber Thus there is no danger of having unsterilized water flowing through the apparatus in case the current should fail During the tests which were made at Marseilles, the authors used a quartz lamp of the Westinghouse-Cooper Hewitt type, with a current of 22 volts and 3 amperes, and the apparatus was run from August 19th until the end of September, working day and night without stopping. It gave an output of 60 cubic meters (78 5 cubic yards) per 24 hours or 32¾ cubic yards per hour During that time there were made eighteen bacteriologic tests of the incoming and outgoing water Before entering the apparatus the (impure) water contained 30 to 300 germs per cubic centimeter (0 061 cubic inch) and 50 to 1 000 coli bacillus per liter (1 057 quarts) After sterilizing we have on the average one germ per cubic centimeter and no coli bacillus in any case. The tests show therefore a run of six weeks, which gives a continuous sterilization of filtered water with a mean output of 25 cubic meters (32 cubic yards) per hour using current at the rate of 660 watt-hours This gives the lowest value which has yet been obtained or 26 watt hours per cubic meter of water (20 watt hours per cubic yard) so that we have a striking progress with the new apparatus

Drifting of the Sun's Family

A Great Unsolved Astronomical Problem

By Arthur K Bartlett

The part of the heavens toward which it is believed the Sun with its entire family of planets comets satellites and meteor streams including of course our own Earth is moving with great velocity is situated at this season directly overhead about 6 o clock in the evening and at a later hour a little farther toward the northwest This is one of the most interesting and important localities in the firmament to astronomers toward which their attention and observation have been directed for many years past

The greatest fact which modern astronomy has revealed is that our whole solar system is now journeying toward the constellation Lyra in the northern heavens and the greatest of the unsolved problems of astronomy is when where and how this journey began and when where and how it will end This journey is unceasing and unchanging and is believed to be at the rate of twelve miles per second or about 300 000 000 miles in a year The question as to whence we came and whither we are drifting is one of vast importance and is still engaging the attention as it has in the past of the leading astronomers of the world for in connection with it is involved the even greater question regarding the structure extent and boundary of the universe

If we look up to the sky directly overhead just after sunset we shall see a star of the first magnitude known as Vega which is located in the constellation Lyra the Harp and is plainly visible through out most of the evening This star next to Capella is the brightest north of the equator and is famous as being the one which in 12 000 years will occupy the important position of the Pole star and will be known by that name in the future The star shines with a bluish white light and may be easily recognized as it is the most conspicuous of any star visible near the zenith at this season

It is toward this star or rather the group to which it belongs that our Earth and the solar system are believed to be moving and this point in the heavens is known to astronomers as the apex of the Sun s way During the last 120 years many astronomers with ever increasing accuracy have sought to determine the point toward which our Sun the Earth and all the other planets are moving For many years the result of investigations was that our system is traveling toward the constellation Hercules in the northern sky But more recent and careful measures lead to the conclusion that the point is located in the nearby constellation Lyra This point is nearly four degrees south and slightly east of the bright star Vega the variations between final measurements maxima and minima of all who have attacked the great and highly complex problem being as much as seven degrees

Owing to the solar drift in space the orbit of our Earth instead of being an ellipse, is really of a corkscrew shape the axis of the corkscrew being in the direction of the constellation Lyra. The great star-cluster in Hercules containing over 6 000 visible suns is not very far away from that part of the sky which we are approaching and it is possible that our system may form a distant part of one of its encircling wisps of star strewn nebulous matter so that in this case we may eventually be drawn into the gigantic cluster

Most astronomers agree as to the general direction of the Sun s motion, but owing to the motion of the stars themselves there is not yet an exact agreement regarding the amount or direction of this motion In a general way we may say that if an observer looks up to the heavens a little southwest of the zenith on a clear evening at this season he may correctly imagine our Earth and the great system to which it belongs as moving toward the star he there sees presented to his view This motion has been going on since the creation and will probably continue for unknown ages in the future

It is true as a recent writer has well remarked That since the beginning we with the Sun have been steadily speeding on and on through interstellar space without once meeting or passing a single lonely stars brings home to our realization as no other consideration can the amazing amplitude of cosmic space the completeness of the isolation of each star from all others and the supreme magnificence of the scale of the stellar universe

Quite recently a new and ingenious theory has been advanced by two astronomers who have attempted to prove that the millions of stars composing our immense universe are moving in two parallel streams traveling in contrary directions and situated in opposite regions of the heavens but their novel ideas have not been confirmed and have received little attention from astronomers who regard them at present as nothing more than an interesting speculation which does not admit of a practical demonstration though it is possible that careful and long continued observations in the future may produce evidence in its favor

The direction of our motion is indicated by the fact that the stars in that part of the heavens toward which we are traveling are observed to spread out and get farther apart while those we are leaving in the opposite part of the heavens close up and gradually approach each other, just as in walking through a forest the trees in front of us are seen to open out while those in the rear appear nearer together as we leave them behind But at present it is not known whether we are moving in a straight or curved path and if in the latter it is so great that it cannot be determined Many stars which have a proper motion as it is called appear to be moving in a perfectly straight path through the sky Among them is the faint star known as No 1830 Groombridge which is believed to be rushing through space at the rate of over 200 miles per second—a velocity so great that the combined attraction of all the masses in the universe cannot stop this star in its swift and solitary flight over the firmament It is known to astronomers as the 'Runaway Star but there are some other stars that are believed to be traveling even more rapidly and none of them exhibits any indications of moving in a curved path

It is interesting to remark that the motion of the solar system plays an important part in the shifting panorama of the heavens Not only do the stars move onward but the Sun moving also carries us continually northward so that our point of view is ceaselessly changing and looking out from the flying Earth we are like people on a ship which is passing by a squadron of other ships. Their evolutions cause them to appear in constantly changing relations to one another and at the same time our own motion shifting the line of sight, produces other changes of view, which increase the complexity of the apparent movements. In short, we are reminded of the remarkable resemblance of the universe to the modern conception of an atom in which the restless corpuscles are speeding in all directions so that an infinitesimal being inhabiting one of those corpuscles would see the other corpuscles shaping themselves into constellations that would be as unenduring as are the figures that the poetic imagination traces among the stars

The famous German astronomer Mädler over fifty years ago advanced the theory that our Sun and all the stars—which are also Suns—are moving in a great orbit around the star Alcyone located in the Pleiades a prominent cluster mentioned in the Bible and known as the Seven Sisters six of which are plainly visible to the naked eye and may be seen at this season just above the eastern horizon about 8 o clock in the evening But Mädler adduced no evidence in support of his views which were not generally accepted by astronomers His ingenious theory was exploded many years ago and astronomers do not at present recognize any particular star as the center around which all the other stars revolve though it is possible that such a center exists somewhere in the universe

The theory that the solar system is revolving around a central Sun was first suggested by Thomas Wright of England in 1750 and later Mädler supposed that he had discovered the exact center of this motion but it is not thought by astronomers that sufficient evidence exists to support this belief and all that can be said to be established at present is that the Sun with its great family of revolving worlds is rushing through space toward a point in the constellation Lyra a familiar group of stars located in the northern heavens and which may be seen to good advantage at this season in the early evening —*Popular Astronomy*

Albinism and Heredity

Dr. and Mrs Charles B Davenport of the Laboratory for Experimental Evolution maintained by the Carnegie Institute at Cold Springs Harbor, Long Island have recently published another installment of their studies on human pedigrees from the point of view of heredity This is concerned with the question of albinism in man and some of the conclusions are of general interest.

So far as the evidence goes the children of albinos are always albinos In albino marriages albino children may be expected without regard to the parentage of the albinos themselves For example in one of the cases given the mother was of negro parentage while the father was of Caucasian parentage, but the offspring was without any pigmentation.

The authors think that in every new case of albinism there is a probability of consanguinity among the parents But this seems to be reasoning backward from the fact that out of a number of cases one-third of all the albinos arose from consanguineous marriages The facts appear to agree with the general rule that a recessive character (and albinism is a recessive character in most animals that have been studied) arises only when both parents carry the same defect "and the probability that both carry the same defect is increased when both belong to the same strain"

The proportion of albino offspring in any family accords with the Mendelian expectation, in the long run, as in other mammals. When one parent is albinic

and albinic offspring occur at all there will be one-half albinic and one-half pigmented In these records there were sixteen albinic and fifteen normal children in five families.

Comparison of the hair coloration in the parentage of albinos with that in the normal population shows a great preponderance of red and auburn hair among the former while dark browns and blacks occur less frequently—65 per cent as compared with 81 5 per cent in the general population Albinos frequently have a blue iris this fact does not appear to be correlated with the preponderance of blue eyes in the parentage of albinos

As to the causes of albinism the authors conclude that it results from the fortuitous union of two germ cells lacking a pigment factor The meaning of this is not very clear It may mean either that the parents bear such germ cells as part of their inheritance—in which case it is but another way of saying that albinism is congenital and is inherited according to definite mathematically calculable probabilities or it may mean that germ cells lacking the pigment factor are present in all individuals in small numbers and their union is a relatively rare event The facts brought out in the study point to the first as being the probable meaning of the authors but in that case we are still in the dark as to the cause of albinism

Paris as a Seaport

A Proposed Canal between Paris and Rouen

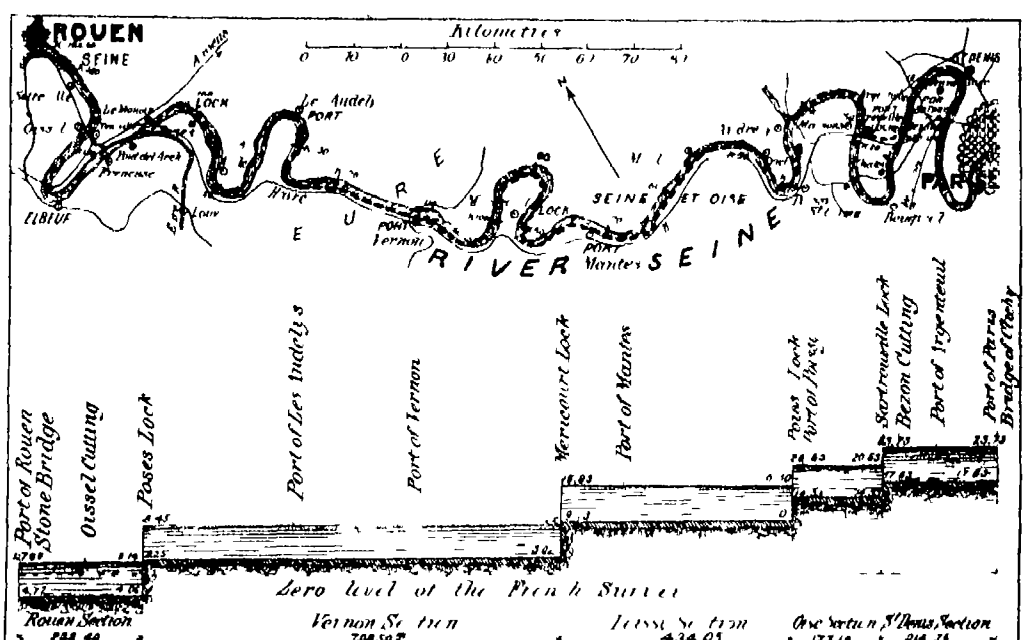
By the Paris Correspondent of the Scientific American

A PROJECT has recently been made to establish a navigable connection between Paris and the English Channel so as to convert the French capital into a seaport and allow vessels up to 3 000 tons draft to unload freight at the docks The cost of this undertaking is estimated at thirty to fifty million dollars Aside from the other obvious advantages which would be derived from such a plan one circumstance which commends it particularly is the fact that it would preclude all possibility of any repetition in the future of such disasters as were recently caused by the flooding of the Seine The idea of turning Paris into a seaport is not by any means new but has of late years been suggested repeatedly One of its principal advocates was M Bouquet de la Grye who in 1886 presented a project to the government suggesting a deepening of the bed of the Seine between Paris and Rouen From this point on to the mouth of the Seine at the English Channel (a distance of 76 miles) the natural depth of the river is sufficient and at the present time vessels travel up the Seine as far as Rouen where the minimum depth is 16 to 18 feet the port accommodating vessels ranging up to 3 000 tons From Rouen to Paris the Seine channel has a depth of only 10 feet It is proposed to increase this to 21 feet so as to enable vessels to travel all the way to Paris by water The channel would follow all the windings of the Seine except for two short cuts where a separate canal would be built so as to avoid crossing the Paris Havre Railroad Our illustration for which we are indebted to *l'Illustration* shows this and other features to be referred to below The total distance of the journey is about 130 miles and would be covered in about eighteen hours with the usual tugboats As regards the width of the river it is 115 feet at water level in straight portions and 150 feet at curves with a radius of less than 5 000 feet By the way of comparison it may be mentioned that the Manchester canal has a maximum width of 119 feet while the Suez canal is 122 feet broad The project in its present form provides for five levels with locks while the section from Rouen to the Channel would be open and would take up the variations of the tide

The plans include twenty four drawbridges The port at Paris would be located at the suburbs of St Ouen The total cost of the engineering work is estimated at thirty million dollars and the total capital invested at fifty millions

This project of establishing a seaport at Paris has now once more come to the foreground and is being discussed in the daily newspapers in Parliamentary circles and also by the municipal council of Paris who are in favor of its adoption Just at this time with the memory of the Seine inundation freshly in people's minds and with the pressing problem of providing measures to guard against such accidents in the future the soil is very favorable for the project to strike root It would save the community the dead cost which would be involved in carrying out any of the other plans that have been proposed for coping with the situation The cost of the project outlined above might quite probably be borne by a private enterprise The municipal council is now however disposed to have the city take the matter into their own hands and has pronounced its sentiment to this effect by a unanimous vote That the city is quite capable of handling such enterprises successfully is evidenced by the very extensive network of the Paris subway, which when completed will have an aggregate length of no less than seventy miles In any case the enterprise would pay for itself A tax of $0 40 to $0 60 per ton gage for sea-going vessels would be collected and also pilot taxes and other rates for river boats, thus yielding a constant return Soon after the enterprise was placed on a working basis, the receipts would, no doubt, pay 5 per cent interest on the capital and yield a handsome surplus. This is a very conservative estimate and takes no account of the great increase in traffic which would no doubt develop in the future. It is estimated, that having regard only to traffic which can be counted on with practical certainty this would amount in the second year of operation to about ten million tons

The project is attracting attention in countries outside of France especially those which now possess large seaports such as Antwerp and Hamburg and should it be carried out Paris will enter into competition with these ports as well as with London so that the entire European traffic will be affected Antwerp would lose a part of its shipping which now comes from Paris and Eastern France Alsace Switzerland and Bavaria It is interesting to note



Plan View and Profile Section of the Proposed Canal from Rouen to Paris

that towards the end of the century recently completed London lost something of its supremacy as a European freight seaport Gradually we have seen Germany Belgium and Holland assuming an independent position of prominence Since 1893 the traffic of Hamburg has increased 80 per cent Antwerp has about the same showing and Rotterdam has gone up by no less than 160 per cent During this period the London traffic increased by only 30 per cent France however has been far behind as regards the merchant marine and could not compete with other leading countries At the present time France sends on an average twenty five million dollars worth of freight to London to have it reshipped from there to different points of the globe Should the new project be carried out this state of affairs will be entirely changed and Paris will rank among the principal seaports of Europe It will receive within its harbor vessels arriving from distant countries A boat which has traveled some ten or thirteen thousand miles coming from Australia South America or China will not hesitate to go a little extra distance and land at Paris instead of London if the conditions of the trade render it desirable

The Independence Bell of Mexico

IN connection with the recent centennial celebration of the independence of Mexico it may not be so generally known that each year on the recurrence of the anniversary which is always joyfully celebrated an interesting scene is to be witnessed in the Mexican capital On the evening of this day President Diaz with his ministers and state officials assemble in the great ambassadors hall in the palace In the great Zocalo before the National Palace is waiting a crowd of many thousands high and low poor and rich In the Biography of Porfirio Diaz compiled by Tweedie the scene as witnessed annually is thus described "It is historic ground on which the crowded masses stand for here many many years ago arose the great Aztec temple Under their feet deeply buried lie altars and urns sacrificial stones and axioms and many heads of the great snake—much has already been brought to light but the earth still covers and envelops a great deal

And now a new race celebrates on this sacred ground the memorial day of their regained liberty The national palace is gaily decorated and the city hall opposite is brilliant in bright illumination In the dark wonderfully beautiful sky the moon shines silvery with a soft radiance surrounded by innumerable glittering stars Below however the bright electric lights gleam on the white shirts and the red hats of the men and the multi-colored rebozos of the women all gaze earnestly at the great brightly lighted clock the hands of which approach the hour of eleven But a minute of the time is lacking when the balcony doors of the palace are thrown wide open and from the apartment within the President makes his appearance clad in festal garb with the broad sash of the President's office across his breast and in one hand the flag of Mexico Behind him are ranged the ministers In the pent up silence of the waiting throng he raises his hand to the cord leading up to the great bell hanging above him and rings on it eleven strokes Deep and full the resounding notes of the great bell tell of the nation's independence as it did on a previous occasion one hundred years ago when it rang from the Dolores church It was brought from there to Mexico in 1896 When the last stroke has resounded the President proclaims in ringing far reaching tones Live the independence and live Mexico The silence is broken the solemn moment is passed and a many thousand throated cheer rings over the great plaza in the stillness of the night

The fact has been established that the bubonic plague is primarily a rat disease and that it is transmitted to human beings chiefly by means of fleas which infest rats Permanent freedom from the rat pest can be secured only by preventive measures The means of ingress to a building must be stopped and the animals deprived of food when they can be easily trapped The bacteria preparations on the market for killing rats may be depended on to kill the rats which eat the prepared bait but they do not set up an epidemic as has often been claimed They are inferior to the poisons and their price is practically prohibitive when used on a large scale

The Destruction of Weeds by Chemical Means—I

An Important Agricultural Problem

By Harold C Long B Sc, Author of "Common Weeds of the Farm and Garden"

During the past twenty years an increasing amount of attention has been devoted to the economic side of insect and fungous pests with a view to their extermination and The Destructive Insects and Pests Act of 1907 gives the Board of Agriculture and Fisheries power to deal with the whole question and to carry out compulsory preventive and remedial measures in the case of such species as they consider of sufficient importance to schedule in their orders[1] The attention of scientific workers has for many years been turned to the necessity of acquiring a thorough knowledge of the life histories of all the worst insect and fungous pests of farm garden and orchard and a vast fund of information has been acquired by a systematic study of individual species Such study in conjunction with experimental work has been necessary in order to eradicate the particular post concerned and here also much has been accomplished even though it be said that much remains to be done

Fig 1—Charlock (*Sinapis arvensis* L) × 2/3 This Weed is Readily Destroyed by Spraying with a Solution of Copper Sulphate or Iron Sulphate

What however is the position in regard to the prevention and eradication of the common weeds of the farm and the garden which annually cause so much loss to the grower of crops? It may be said that a good deal has been done to enable the unbotanical worker to identify species and a few practical botanists and agriculturists have offered sound advice as to the mechanical destruction of weeds Yet the information available is still quite inadequate and while some of the highly farmed lands are more or less weedless the majority of farmers meet with two or three species of weeds which they experience extreme difficulty in combating The question of weed eradication is one of real difficulty and when we bear in mind the fact that many serious insect and fungous pests are supported and distributed by weeds it assumes an importance which the entomologist and mycologist would do well to recollect Prof Somerville has written[2] Using the term in its widest sense *good cultivation* will be found to be the best protection that the farmer or gardener can offer his crops against insects and good cultivation includes the destruction of weeds In many countries the importance of destroying weeds has long been officially recognized and acts have been passed requiring the destruction of specified weeds In Great Britain however the only laws of the kind refer to Ireland and the Isle of Man

Fig 2 Persicaria or Redshank (*Polygonum Persicaria* L) × ½ This is a Pest of Good Arable Land and Gardens It Has Been Quite Destroyed by a 4 Per Cent Solution of Copper Sulphate (100 Gallons Per Acre)

THE PREVALENCE OF WEEDS

We have said that some highly farmed lands are more or less weedless but it is undoubtedly true that most farms are far more weedy than they either ought to be or need be In the third week of August 1909 we found in an area of perhaps a hundred square yards of a wheat field no less than twenty nine species of weeds the majority of which were among the most troublesome of all (including the species illustrated in Figs 1 5 6 and 8) Similar cases could be quoted We consulted twenty nine experts in different parts of the country from the North of Scotland to the South of England and species of couch or twitch were included thirty two times among the six worst weeds of arable land charlock and runch twenty-eight times docks sixteen times thistles sixteen times coltsfoot thirteen times and so on As regards grass land thistles were regarded as the worst in twenty two cases buttercups sixteen Yorkshire fog (*Holcus lanatus* and *H mollis*) nine docks eight and so forth These figures show that the species named are not only widely distributed but in the cases mentioned are real pests of farmers In good garden soil well cultivated for three years we found one thousand and fifty seedlings in a square yard on May 17th 1909 and of these seedlings six hundred and fifty four were those of creeping buttercup one hundred and seven *Poa annua* and sixty were a species of dock Many seedlings were subsequently destroyed on the same square yard Plenty of other evidence as to the prevalence of weeds could be adduced

Fig 3—Petty Spurge (*Euphorbia Peplus*) Natural Size This Weed is Very Common and Plentiful in Some Districts It Appears to be Protected From Spray Fluids by a Glaucous Bloom on the Leaves

THE HARM DONE BY WEEDS

Many pages could be written dealing with the losses caused by weeds but the matter can only be briefly mentioned here It may be stated however that weeds take up the space which should be occupied by the cultivated plant weeds rob the crop of food and moisture and of air light and heat, they hinder thorough cultivation harbor injurious insects and fungi are parasitic on crops may be poisonous stop up drains, and their seeds may very seriously reduce the value of those of agricultural plants which hence require very thorough cleaning, involving considerable expense In short, the cash losses due to weeds are very serious The following examples will suffice

(1) The nitrogen in the dry matter of Persicaria (*Polygonum Persicaria*) was found to equal nearly 20 per cent of albuminoids[3]

(2) A twenty five bushel crop of wheat was found at the Agricultural Experiment Station of Cornell University to transpire (during growth) five hundred tons of water Weeds probably transpire to a somewhat similar extent

Fig 4—Corn Cockle (*Agrostemma Githago* L) × 2/3 Not Only a Weed in the Usual Sense but it is Poisonous in a Degree Spraying is Partly Effective and Generally Prevents Seeding (See Text)

(3) Charlock (*Sinapis arvensis* L) and other cruciferæ are hosts for the Turnip Flea Beetle or Fly (*Phyllotreta nemorum*) the Turnip Gall Weevil (*Ceutorhynchus sulcicollis*) the Diamond Back Moth (*Plutella maculipennis*) Finger and toe Turnips (*Plasmodiophora brassicæ* Wor) *Peronospora parasitica* De Bary and other pests

(4) Wollny has placed the annual loss of crops due to weeds in Bavaria at an average of 30 per cent[4] Korsmo found the percentage loss in money value on a weedy compared with a clean plot of barley to be 46 per cent and in the case of potatoes 49 per cent.[5] Experimental plots at University College Farm Reading showed that with two hoeings only after "singling mangolds yielded over thirty-seven tons per acre but when unweeded the yield was only slightly over sixteen tons per acre

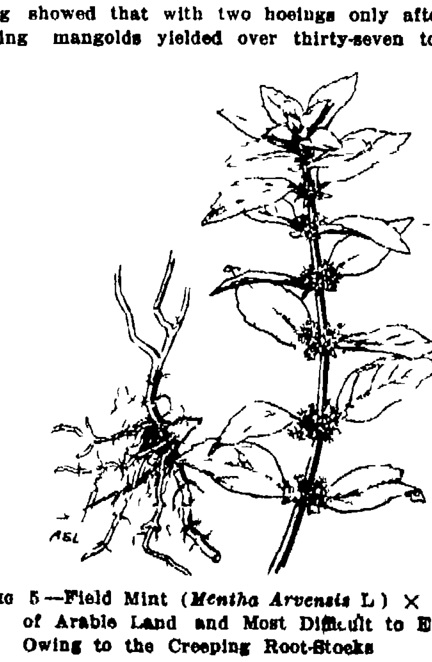


Fig 5—Field Mint (*Mentha Arvensis* L) × ½ Pest of Arable Land and Most Difficult to Eradicate Owing to the Creeping Root-Stocks

(5) If the real value of agricultural seeds, owing to impurity and low germinating power be only 76 per cent. then the (initial) loss in cash would be 24s ($5 83) in £5 ($24 25) if bought at the rate for best seed

THE DISTRIBUTION OF WEEDS.

Regarding the manner in which weeds are distrib-

* Knowledge

[1] The Destructive Insects and Pests Order of 1910 schedules sixteen destructive insects and pests whose presence on any premises must be notified to the Local Authority or to the Board of Agriculture and Fisheries.

[2] Farm and Garden Insects, p. 20.

[3] Stutzer and Seidler Fühling's Landw. Zeitung, June 15th, 1908, p. 420.

[4] Fr Meier-Bode, Die Bekämpfung der Acker-Unkräuter.

[5] Tidsskr. Norske Landbr 10 (1903).

weeds it may be said shortly that the seeds are scattered in the same general way as with other wild plants—by transportation through the agency of man, railways, shipping, and so on, by rivers and floods, by birds and wild animals, by wind (owing to extreme lightness of the seeds or to their bearing flight organs), and by seeds adhering to animals (or man) by means of hooks, and so forth In other cases broken portions of the rootstock may be transported and give rise to new centers of infestation

CO-OPERATIVE DESTRUCTION OF WEEDS

We may now consider the means at the disposal of the farmer for the purpose of destroying weeds and all may be covered by co-operation which should be devoted to (1) The supply of pure seeds free from the seeds of weeds, (2) the mechanical destruction of individual species which may prevail in a given district by means of the ordinary routine methods practised on the farm as well as by special measures, and (3) the destruction of weeds by spraying

If farms are to be kept free from weeds and farmers are to be prevented from causing infestation of a neighbor's farm by neglect of their own it must be by compulsory eradication or by co-operation—*farmers must work together*

Regarding (1) it is clear that a combination among say fifty farmers in a district will enable them to purchase large lots of high class seeds at a fair price under guarantee and to have them sampled and tested A pure seed supply will thus be insured

In relation to (2) it may be suggested that mechanical destruction should include co operative eradication of docks and thistles by the use of docking irons spuds thistle cutters regular cutting of many weeds by hand and by power machines cutting of weeds on

Fig 6—Knot Weed (*Polygonum Aviculare* L) Reduced A Serious Trouble to Farmers Often Occurs in Incredible Quantities on Light Sandy Soils

waste lands and roadsides to prevent the formation and distribution of seed the collection of seed shed at harvest time by the use of box attachments to reapers and binders thorough cleansing of thrashing machines before they go to the next farm co-operative purchase and use of surface weeders like the poppy killer American weeder and so forth A year or so ago Dr Ewart government botanist of Victoria suggested that school children should be offered prizes for collecting certain weeds A police magistrate offered prizes and 12 000 plants of Ragwort (*Senecio Jacoboea*) were brought in during the first four days the number quickly rising to 20 000 plants

(3) The destruction of weeds by spraying is of most interest and is dealt with below

THE DESTRUCTION OF WEEDS BY SPRAYING

It is only in recent years that attempts have been systematically made to destroy weeds by means of chemical substances these having been chiefly applied in the form of simple solutions The method appears to have originated in France, where M Bonnet found, about 1896, that a solution of copper sulphate destroyed charlock (*Sinapis arvensis* L.) without permanently injuring the cereal crop among which it grew Attention was directed to this fact in the press, and a host of experimental trials was soon conducted, the result being that the facts were quickly established, and in 1900 a leaflet on the destruction of charlock by means of spraying with the sulphates of iron and copper was issued by the Board of Agriculture. Forty gallons of a 4 per cent solution of copper sulphate or a 15 per cent solution of iron sulphate may be sprayed over an acre of the crop when the charlock is about three inches high and if the operation be properly performed during suitable weather the weed will be destroyed and the cereal remain practically uninjured

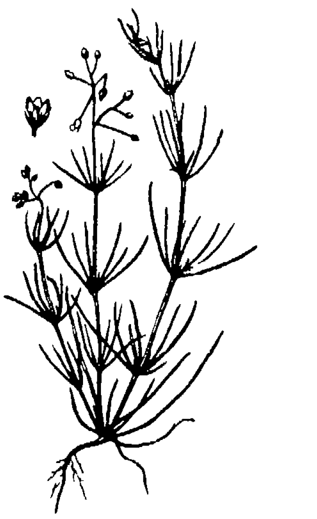

Fig 7—Spurrey (*Spergula Arvensis* L) × 2/3 This Plant is One of the Most Troublesome Weeds on Light Sandy Soils Being an Annual it is Only Necessary to Prevent the Ripening of Seed It Has Been Found That a 5 Per Cent Solution of Copper Sulphate Destroys It

It is believed that the rough broad more or less horizontal leaves of charlock catch and retain the solution while the narrow smooth practically vertical leaves of the cereal throw it off and hence are not damaged In this connection there is room for further investigation and it may be commended to the chemist and botanist alike as a source of interesting research

Since the introduction of spraying for the destruction of charlock a number of experiments has been carried out and many investigators have made trials with a variety of plant poisons the effects of which have been observed when applied to a number of species of plants Though the results are interesting and some information has been obtained they are by no means conclusive but it will be useful to refer here to some of the experiments and their results

In the course of experimental work in spraying charlock (Fig 1) with iron sulphate in 1898 it was found by Prof Somerville that both at the North umberland County Farm Cockle Park and in the grounds of the Durham College of Science (New castle on Tyne) all rough leaved plants such as thistles and to a lesser extent coltsfoot (*Tussilago Farfara* L) were crippled while glaucous plants like species of *Chenopodium* were not affected

It is well known that broad leaved plants are often scorched when nitrate of soda is broadcasted on them It was stated ten years ago that a solution of 15 to 40 per cent of nitrate of soda and sulphate of ammonia sprayed on young charlock plants in the early rough leaf stage caused them to begin to wither in a couple of hours Chloride of potassium is said to have a similar effect on charlock when applied in solution

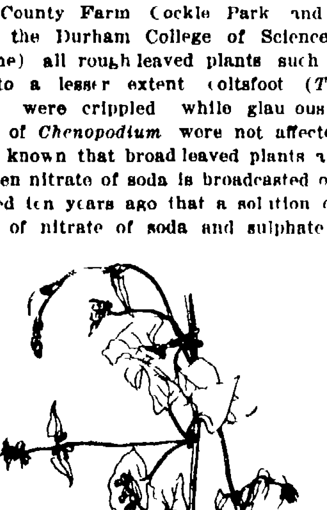

Fig 8—Black Bindweed (*Polygonum Convolvulus* L) × 2/3 A Most Mischievous Annual the Twining Branches of Which May be Several Feet Long and Drag Down Cereal and Other Crops Partly Destroyed by Spraying With Copper and Iron Sulphate Seeding Being Largely Prevented

About seven years ago Mr G F Strawson stated in regard to copper sulphate that It is now admitted that mangolds as well as beans peas tares wheat oats and barley can be sprayed without injury and the charlock among them destroyed and that the spraying does no harm to the young grass seeds clover sainfoin and so on growing in the crop Evidence on this point however is conflicting as we shall see and in Germany V Rümker only last year held that spraying sugar beets with sulphate of iron is hazardous (There may be some difference in sensitiveness between mangolds and sugar beets and also in the methods of spraying) Only this summer Mr Strawson repeats that mangolds have been constantly sprayed during the last seven or eight years and that he has never heard of a single instance where the crop was appreciably injured He also repeats that corn tares sainfoin clover beans (and peas in most cases) can be safely sprayed with pure copper sulphate to eradicate charlock The statement regarding mangolds was confirmed a week later in the same journal by another writer

A good deal of experimental work in spraying has been conducted at the North Dakota Agricultural Experiment Station by Mr H L Bolley and some of his results are interesting His experiments commenced in 1896 with copper sulphate and mercuric bichloride and the results in killing charlock without injury to wheat are described as surprisingly successful Bolley found that the best time to spray is when the crop and weeds are making rapid growth that slow growing weeds are hard to kill and that the more succulent the weeds the more easily are they destroyed Sodium arsenite in preliminary ex

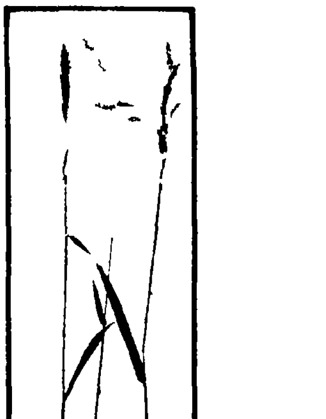

Fig 9—Yorkshire Fog (*Holcus Lanatus* L) A Great Trouble in Many Pastures Very Common and Widely Distributed A Hairy Grass Refused by Stock

periments was usually much more efficient as a weed destroyer than the sulphates of iron and copper it acts quickly destroying the weeds (apparently charlock and king head) even though rain follows within a few hours Referring to the two sulphates Bolley concludes (in Press Bulletin No 27 1907) These substances are recommended here for mustard and king head and will dispose of other annual weeds which they thoroughly wet including Red River weed common rag weed and pepper grass and will much weaken and retard the development of the French weed wild buckwheat black bindweed rose bushes wild docks Canada thistle and many other of the destructive weeds which invade cereal crops In Bulletin No 80 (1908) Bolley shows that at the North Dakota Station they have successfully used in various sorts of weed eradication work common salt sulphate of iron sulphate of copper corrosive sublimate and sodium arsenite but because of its cost and its extremely poisonous character the corrosive sublimate (mercuric bichloride) is not recommended for weed killing while the arsenite must be used with great caution

(To be continued)

Tinning Large Articles of Copper Brass Cast and Wrought Iron (according to Bonsfield)—Pickle the articles in dilute sulphuric acid Then place them for 8 hours with 64 parts of zinc in pieces in a composition heated by steam to 158 deg F and made by dissolving 15 parts of cream of tartar in 3 200 parts of water Neutralize with 2 parts of precipitated chalk and add 7 parts of tin salt dissolved in 320 parts of water

Jour Dept. Agric., Victoria, 1908

Jour d'Agric. Pratique, 1897

As stated below, Mr H. L. Bolley started spraying investigations in the United States in 1896, and says they were perhaps the first experiments of the kind conducted in any country

Solar Power

To the Editor of the SCIENTIFIC AMERICAN

I have read with much interest the articles appearing in the SCIENTIFIC AMERICAN of January 21st 1911, and the SCIENTIFIC AMERICAN SUPPLEMENT for January 21st 1911 Previous to the reading of these articles in the SCIENTIFIC AMERICAN I had read them in one of the London scientific papers

You head the article in the SCIENTIFIC AMERICAN as follows Whereas Fessenden assumes that water can be raised by the sun s rays to its boiling point the highest temperature which is mentioned in scientific literature within our knowledge is 65 deg Cent or 149 deg Fahr

We have in an actual business way anticipated practically everything Prof Fessenden writes about To prove this we are sending you one of our catalogues published some three or four years ago Since the publication of this catalogue we have greatly improved the absorbing qualities of our heater and have greatly simplified the construction

We have spent $75 000 in the commercial exploitation of the sun s rays and have built six different sun motors and have proved them out in an absolutely scientific way Prof R C Carpenter of Cornell University has gone into the matter slightly and admits that what we say is true as far as he can go Mr A S F Ackermann M E of London has tested the steam producing qualities of our sun heater by actual careful tests spreading over three different experiments and he has indorsed the fact that we can get the amount of steam out of the amount of area which we have assumed

You are no doubt right that you have not seen higher temperatures than 149 deg Fahr in scientific literature The fact however remains that we have obtained in this high latitude an apex temperature of 267 deg Fahr and the production of 212 deg atmospheric steam is an easy matter for us on any clear sunshiny day in this high latitude In the tropics where we intend to use the sun engine we will no doubt get greatly higher temperatures than this In this latitude in summer time between 10 o clock in the morning and 3 o clock in the afternoon atmospheric steam (212 deg Fahr) can be produced in paying quantities

The problem of constructing a sufficiently cheap sun heat absorber is not a serious one We accomplished this over three years ago The problem was to find a steam engine which will use the steam (or boiling water) produced by the sun heat absorber in a proper way The assumption that a low pressure turbine will do this is entirely wrong It is true a low pressure turbine will run with the steam generated directly or with the steam caused by the evaporation under a partial vacuum of a 212-deg temperature water

Owing however to the impossibility of getting a turbine to work with proper efficiencies with such widely varying quantities of steam we have given this idea up after trying three different turbines

We were therefore compelled to invent a low pressure reciprocating engine which uses with equal efficiencies (based on the thermal efficiency) the steam produced by the sun s rays at all times of the day from 7 o clock in the morning until 5 o clock in the afternoon in the tropics

We have reason to believe that we are the only ones who have ever actually built practical sun power plants Everything we have thus far heard from has either been fictitious or has been based on a very short and erratic series of operations and many breakdowns

We have unquestionably solved the problem of producing sun power However we have found that in order to produce sun power plants of 25 horse power and over up to 100 000 horse-power—the larger the better—the total cost of construction per brake horse power including everything is $300 This will produce a power plant which gives fuel for absolutely nothing cuts down the labor to less than a quarter and cuts down the wear and tear to less than one tenth of the best modern steam plant

Counting the interest on the investment we find that we can compete with $3 coal in the tropics at this stage of our knowledge We cannot expect to bring sun power at once to an apex We see many ways ahead of cheapening construction and increasing efficiency and have no doubt that another ten years of experience will enable us to compete with $1 coal in the tropics

It must be remembered that a sun power plant which in the tropics can compete with $3 coal (counting in the greater interest due to the greater investment) is at the present moment a very good commercial investment. There is room for a million horse-power in the true tropics where coal is above $5 per ton, and room for easily an equal amount where coal is from $5 to $20 per ton Those are of course, the places where the first sun-power plants will be exploited

Prof Fessenden s idea of storing power by pumping water to a great height in tanks, is correct as far as it goes But we can store a much greater power at greatly less expense by storing up the boiling water in the manner shown in our catalogue.

The sun engines which will be built during the coming five to ten years will be mainly irrigation engines where the quantity of water pumped need not be of necessity steady during the twenty four hours If the sun power plants are used for irrigation the problem becomes much simpler because in the first place the water used for irrigation can be pumped through the condenser and then into the reservoir or on to the land and then the atmospheric steam evolved can be used direct in the peculiar reciprocating engine which we have invented

We have invented a reciprocating engine which has on low pressures far greater economy than any turbine or reciprocating engine Prof Carpenter tested this engine very thoroughly and from his report dated February 24th 1910 I will quote the following

I do not know of any other type of prime mover steam engine or turbine having the same capacity which could have done as well I should certainly have expected 20 to 30 per cent higher steam consumption from any other piston engine and 50 to 60 per cent from any steam turbine of the same capacity

On sending Prof Carpenter s complete report to London for the purpose of securing money the London company sent over here Mr A S E Ackermann B Sc (Eng) A C G I A M I C E M R S I who went over Prof Carpenter s tests and showed an even better steam economy owing to the fact that he ran his engine to higher power by increasing the number of revolutions Mr Ackermann s best result was 26 5 pounds of steam at atmospheric pressure per brake horse power

Remembering that the engine tested was only a 30 horse-power reciprocating engine you will find this economy quite remarkable There are few 800 kilowatt turbines than can equal it and the most of the 800 kilowatt turbines this little 30 horse-power reciprocating engine has beaten When the size of this engine is brought to the 800 kilowatt mark the economies would of course be much greater

To recapitulate we have this much desired sun power idea above the experimental stage and we are going into the construction of actual working engines We are now constructing a 25 horse-power sun plant which will be ready for testing on July 1st of this year here in Tacony It will be run until everything is found correct and then sent to Cairo Egypt and tried there

The reason why we can count on certain results is that this will be the final one of a long series all of which gave good results and every succeeding one of which was better than the previous one The great handicap that the sun power inventor has is that the ordinary business man will not invest money in a scheme of this kind until he has been most convincingly shown The money used heretofore has come from myself and personal friends who have made good dividends from other inventions made by me

There is a great similarity between sun power and aviation You will at once admit that any business man approached several years ago with a view of purchasing stock in a flying machine company would have feared the sanity of the proposer After it has been shown conclusively that it can be done there is now no difficulty in securing all the money which is wanted and very rapid progress in aviation is from now on insured We will have to go through this same course

You have published in your paper a great deal of my work and a number of my inventions for instance the building of the City Hall tower of Philadelphia the wire glass machines the Simplex piling operations the wool-degreasing machines and you did publish my first ether sun engine

Philadelphia Pa FRANK SHUMAN

American and Argentine Dreadnoughts

To the Editor of the SCIENTIFIC AMERICAN

The interesting article in the June issue of the Navy and the reply thereto in the SCIENTIFIC AMERICAN of August 27th concerning the relative merits of the Argentine battleships Rivadavia and Moreno and the American battleships Wyoming" and Arkansas give rise to many interesting comments

Whether the Rivadavia or the 'Wyoming" will prove to be the better vessel cannot be positively decided until the two vessels have been launched and completed Still with the data at hand, one can see that the estimated speed of the 'Rivadavia (22½ knots) is two and a half knots greater than that of the Wyoming This in itself is a heavy handicap on the American vessel and would put her in an inferior class when speed alone becomes the issue.

Turning to the displacement, we find that the Argentine vessel has the advantage by 3,957 tons over the Wyoming's' displacement of 27,243 tons. The coal supply of the 'Rivadavia (4,000 tons) is three-quarters greater than that of the other vessels. This would enable them to keep the sea longer, besides allowing a wider radius of action.

In the event of a naval campaign by a squadron of Rivadavias against a squadron of "Wyomings," the greater radius of action and superior speed of the former might decide the fate of a campaign, and compel the slower vessels to adopt a more cautious plan of attack so as to husband their inferior resources.

Maneuvers in naval warfare are often as decisive as a pitched battle and far less expensive in the matter of blood and treasure The presence of a 'fleet in being has often changed the entire nature of a campaign as in the case of Lord Torrington After the battle of Beachy Head in 1690 that officer's disposition of his fleet no doubt prevented De Tourville, the French admiral from moving troops across the channel into England Again during the Russo-Japanese war Admiral Essen s Vladivostock squadron raided the east coast of Korea and sank several Japanese transports Subsequently these fast vessels moved over to the Pacific coast of Japan and threatened Yokohama. Although these movements did not make Togo release his grip on Port Arthur or compel Oyama to abandon the advance on Liao-Yang Kamimura s Japanese squadron was compelled to remain in the Straits of Tsushima so as to protect the troopships going to Manchuria Kamimura s four armored cruisers would have been a welcome aid to Togo at the battle of August 10th 1904 Had fortune continued to favor Essen and Bezobrazoff they might have accomplished a great deal more and perhaps changed the character of the war

Again in our war with Spain the formation of the Eastern Squadron under Commodore Watson for a descent on the Spanish coast helped to compel the slow Spanish fleet to abandon the voyage to Manila and return to Spain Watson s fast squadron although it never left West Indian waters nevertheless had a powerful influence in bringing the war to a close In this way it can be easily seen that the fast Argentine vessels would possess considerable advantage over their American contemporaries when operating against each other

In the matter of the fire superiority the vessels are equally armed in the main batteries but the arrangement of the turrets gives the Wyoming' a weaker head-on fire than the Rivadavia The former vessel can train only two turrets directly ahead on a line with the keel while the latter can support her two forward turrets fire by the two midship turrets one on each side of the vessel These have an arc of forward fire of ninety degrees In the American vessels the two midship turrets have only an arc of fifty degrees forward fire and they would thus become masked as the line of fire became dead ahead

Turning to the broadsides the two vessels are practically equal while in their stern fire almost the same condition prevails In the latter case four turrets would have a direct fire On the American vessels the line of fire would be on a line with the keel while on the Argentine vessels the stern fire would be as powerful as the forward fire and owing to her *echeloned* turrets amidships the fire superiority would be identical Hence as long as the *echeloned* turrets remained intact the Rivadavia could fight on her own terms while to equal her the Wyoming would have to present her stern fire or else maneuver into a broadside position and rake her opponent

When we come to the matter of armor protection we can simply keep in mind Admiral Farragut s maxim The best protection against an enemy s fire is a well-directed fire of your own Armor while essential, is not absolutely a security against gun fire when we consider that the heaviest shot are capable of penetrating very thick armor

In the event of battle good seamanship together with good tactical management and gunnery would decide the affair although it clearly appears that the Rivadavia would have the advantage at the start.

Brooklyn N Y GERALD ELLIS CRONIN

A handy way to remove a wood screw that has stuck and is so tight that there is danger of twisting off the head is as follows Heat a poker or a piece of round iron red hot, and hold it against the screw head for a little while Wait a few minutes for the screw to cool off when it will be found that the screw can be removed quite easily with the same screw driver that just previously would not perform the work. The explanation is simple. The red hot poker heats the screw the screw expands and makes the hole it is in just a bit bigger The screw then cools down and resumes its original size, leaving the hole in the wood a size larger The writer has given this little kink a fair test in taking screws out of some oak boards that were built in a refrigerator where the wood had become set around the screws.

A printed copy of the specification and drawing of any patent in the foregoing list or any patent in print issued since October 4th 1859 will be furnished from this office for 10 cents provided the name and number of the patent desired and the date be given Address Munn & Co Inc 361 Broadway New York.

Canadian patents may now be obtained by the inventors for any of the inventions named in the foregoing list For terms and further particulars address Munn & Co Inc 361 Broadway New York.

Some Mountain Winds and Their Names

BY FITZHUGH TALMAN

The march of human knowledge is from the particular to the general and the nomenclature of science moves in the same direction. The individual manifestations of a natural law are first observed and separately named the law itself comes to light later through the process of induction and science then finds itself burdened with a multitude of names for one and the same phenomenon

This fact is well illustrated in the history of wind nomenclature In the modern scientific classification of winds a score of names suffice for them all in an earlier generation Aeolus ruled over a populous kingdom and his subjects possessed for our forefathers an individuality that was expressed in a nomenclature of bewildering magnitude The wind called Euroclydon was to St Paul and his contemporaries an isolated and distinct entity that no one thought of linking up with the general atmospheric circulation of the Mediterranean and Milton's herald of the sea thought it necessary to question every gust of rugged wings about the fate of Lycidas when he might better have applied at once to headquarters i e to the center of the cyclonic storm that was sweeping the British seas when the unfortunate young Cantabrigian came to grief

We now know that all mountain winds can be classified as (1) local breezes of diurnal period and (2) local modifications of more general winds To the former class belong (a) the normal mountain and valley breezes due to the alternate heating and cooling of the valley bottom and the mountain slopes and blowing up valley by day and down valley by night (b) breezes of reverse direction—down valley by day and up-valley by night—which occur when the circulation of a valley is overpowered by the more active circulation of an adjacent valley—a phenomenon of which the Malojawind of the Upper Engadine is the classic example and (c) down-cast diurnal winds which occur when the mountain-sides are covered with snow and ice and hence are colder than the surrounding air Winds of the last class are typified in the *nevado storms* of the Andes described by Moritz Wagner and I propose to call these *snow-winds* in the absence of any other well established generic name Such winds are as Hann has told us regularly observed at the foot of glaciers on warm days

Of the general winds that take on special characteristics when they traverse a mountainous country there are two important groups each of which bears the name of its most prominent representative These are the *foehn* winds or *foehns* and the *bora* winds which might with propriety be called *boras* Both the foehn and the bora are descending winds or *fall winds* but while the former is intensely heated and dried in the process of its descent the latter which blows from a cold inland mountainous region to a relatively warm coast although also warmed to some extent retains the character of a cold wind The explanation of these processes is given in every treatise on meteorology or physical geography and need not be repeated here

The alternating day and night breezes of mountain valleys may be so gentle as to escape notice or so strong as to excite interest and wonder according to the configuration of the valley and the sharpness of the contrast between the diurnal and nocturnal temperatures Before the days of scientific generalizations on this subject such of these breezes as were especially strong and regular were apt to be given individual names a great number of which still survive

The local winds of the western Alps were first thoroughly studied about seventy years ago by J Fournet and to him we are chiefly indebted for our knowledge of their nomenclature The most famous of these breezes is the *pontias* This is a cold nocturnal wind blowing out of a narrow valley that opens upon the plains of the Rhone near the town of Nyons, which once bore the sobriquet *Pontias* due to the presence in its neighborhood of an old Roman bridge (pons) This *ventus pontiacus*—also called *le vent de St Césarée d'Arles* has been known from time immemorial and was the subject of many speculative disquisitions before modern science was brought to bear upon it Tradition ascribes the origin of this wind to the beneficence of St Cæsarius Archbishop of Arles who is said to have brought it from the sea in a glove for the purpose of improving the fertility of the valley In reference to this legend an alternative etymology of the name *pontias* derives it from the Greek and Latin *pontus* the sea The peasants claim that the olive trees upon which this wind blows produce fruit of a superior quality and that its cessation is an omen of pestilence

In the same valley with the *pontias* the up-valley day breeze is called *vesine* a name which Fournet tells us means bad wind Good authority however derives this word from the name of a former division of Provence viz Venaissin from the direction of which the wind blows

Another local breeze of the French Alps is the *solore* or *solaure*, which blows at Saillans, along the narrow valley of the Drôme Its diurnal periodicity is expressed in the name which is equivalent to *sol* + *aura*, sun breeze To the western Alps also belong the *vent du mont Blanc* (Mont Blanc wind), the *aloup de vent* (wind wolf), blowing by night down the valley of the Brevenne and the *joran* blowing down from the Jura mountains (whence the name) to the shore of Lake Geneva The *joran* Forel tells us does not blow out onto the lake but another wind does, viz., the *morget* which is not a mountain breeze but a regular nocturnal land breeze alternating with a diurnal lake breeze called the *rebat* The *morget* and the *rebat* are the homologues of the alternating land and sea breezes of ocean coasts The *morget* is named from the town Morges *rebat* is evidently from the French *rebattre* in some one of its senses

The Italian lakes are especially rich in local wind names only a few of which can be mentioned here On Lake Como the day breeze blowing toward the head of the lake is called *la breva* the opposite night breeze *tivano* On Lake Garda, and in the neighboring Etsch valley the regular day breeze blowing up-valley is the *ora*—probably an archaic form of the Italian word *aura* breeze The northerly night breeze is called *sover* or *sopero* i e upper wind Just as on the lakes of the Austrian Salzkammergut the night wind blowing from the upper end of the lake is called *Oberwind* its opposite by day being the *Unterwind* or *Niederwind* Lake Garda has a score of other wind names a list of which is given by F Denza in his Italian version of Scott's Elementary Meteorology on page 498

Of the many other local breezes that have special names I shall mention only the *Wisperwind* the cold night breeze that blows out of the valley of the Wisper a small affluent of the Rhine and the *Erlerwind* which blows in the Inn valley north of Kufstein in the Tyrol

Turning now to winds belonging to the more extensive circulatory systems of the atmosphere we come first to the *foehn* which is undoubtedly the most interesting of mountain winds The word *foehn* became naturalized in English before the German umlaut lost its e and the old spelling is generally retained in English texts though the modern German form *föhn* is also met with An argument in favor of the older form is the fact that the transition from *fohn* to *fohn* would be temptingly easy at least to cis Atlantic writers—and especially to cis Atlantic printers—and antiquated German is preferable to a barbarous anglicization *Fön* is an alternative spelling in German

The history of the word *foehn* has been traced by R Billwiller and is a striking illustration of the vicissitudes that many wind names have undergone In the classical Latin wind rose the west wind was called *favonius* i e the beneficent wind (from the verb *faveo*) so called because it brought mild weather melted the snow in spring and promoted the growth of plants While to the mariner, in all ages the direction from which a wind blows is its most important characteristic the agriculturist is more interested in its physical qualities and their effects It is therefore not surprising that the Italian peasants who migrated to the northern slopes of the Alps transferred the name *favonius* to the wind that had the physical characteristics of the west wind in Italy and this was the warm wind from the south In the Rhaeto-Romanic dialects *favonius* became *favougn favoign fuogn fuin* etc. later Germanized into *foehn* The evolution of the word however did not stop here When the scientific study of the foehn was begun its high temperature was accounted for by the hypothesis that it was a sirocco wind from the African deserts which after traveling northward at a great altitude was in some manner brought down to the earth after passing the Alps Dove thought it was an anti trade wind from the Caribbean Sea So far the name belonged exclusively to the Alpine region The true theory of the foehn was given by Espy and more fully by Hann It was discovered that the foehn was simply a descending air current, heated by compression and dry in consequence of having lost its moisture through condensation and precipitation during a previous ascent Given this conception of the foehn, it was inevitable that the same phenomenon must occur in other parts of the world, and it was in fact found that the foehn is fairly common in mountainous regions everywhere and has in many cases been given local names—*chinook* in western America, *zonda* in Argentina *autan* in the south of France etc Thus *foehn* became a generic name for a very numerous class of winds In its widest extension the word is not even limited to mountain winds but is applied to *any* current of air that is heated and dried by compression during descent, and meteorologists to-day write of the anticyclonic foehn that gives warm weather and clear skies to the belt of descending air bordering a barometric depression

The Alpine foehn has a large nomenclature both scientific and popular A *wilder Föhn* is especially violent a "*Dimmerföhn* relatively weak. The *foehn wall* (*Föhnmauer*) is the fringe of cloud that forms along the crest of the mountains over which a foehn is blowing "Foehn sickness" is alleged to be experienced by some people during the prevalence of this wind. The foehn is nicknamed "*Schneefresser*" ("snow eater"), because it causes the snow to disappear with marvelous rapidity, the Alpine peasants have a saying that a day of foehn is as good as a fortnight of sunshine. The name snow eater" is likewise applied in western America to the chinook. In northern Tyrol and Vorarlberg the foehn is called "*Türkenreifer*" ("maize ripener), in Graubünden its sobriquet is "*Traubenkocher*' (grape cooker'), in some parts of the Tyrol it is *Mailänder*, because it blows from the direction of Milan

With regard to the American *chinook* it need only be noted here that while the scientific chinook is always a foehn the chinook of popular parlance may be almost any warm wind Similarly, in Argentina the name *zonda* is applied not only to the westerly foehn wind, but also to a northerly sirocco wind As to the etymology of these words, *chinook* is from the name of a family of Indian tribes settled along the Columbia River but exactly why their name was applied to the wind is unknown *zonda* is from the village of Zonda, in South America.

The *autan*, of southern France is a recent addition to the foehn family i e, the fact that it is a foehn has only lately been discovered through the investigations of E de Martonne professor of geography at the Sorbonne It is a violent dry wind from the south or southeast, prevailing on the Atlantic slope of Haut Languedoc and in eastern Aquitaine and has been found to be really an extension of a moist wind the *marin*, blowing from the Mediterranean on the opposite side of the mountains

In a recent letter to the author M de Martonne sends an interesting piece of information not heretofore published concerning the *autan* One of his philological colleagues has investigated the etymology of this word, and finds that it comes from the Latin *altanus* which usually meant a wind from the sea (*ex alto*) This seems to argue that the identity of the *autan* with the *marin* was recognized from early times However, this conclusion must not be too hastily accepted since the word *altanus* was undoubtedly variously applied by classical writers and we have seen in the case of *favonius* how easily the ancient names of the winds were diverted from their original meanings

As to the *bora* which as a generic term includes the *mistral* of southern France I shall say only a word regarding the terminology of the Adriatic bora, which is the type specimen of its class. A moderate bora is called *borina* a very heavy one *boraccia*—and whoever has experienced the ferocity of a boraccia will bear witness that the Italian pejorative suffix is fittingly applied The wind blows in violent gusts called *refoli* or *raffiche* and fills the air over the sea with a mist of driving spray the *fumarea* or *spalmeggio*

TABLE OF CONTENTS

Industrial Alcohol

Its Manufacture and Uses

By JOHN K. BRACHVOGEL, M.E.

Size 6¼ x 9¼ inches. 528 pages.
107 Illustrations. Price $4.00, postpaid.

THIS is a practical treatise based on Dr Max Maercker's "Introduction to Distillation," as revised by Drs. Delbruck and Lange It comprises raw materials, malting, mashing and yeast preparation, fermentation, distillation rectification and purification of alcohol, alcoholometry, the value and significance of a tax-free alcohol methods of denaturing its utilization for light, heat and power production, a statistical review, and the United States law This is the latest and most authoritative book published on the subject and is based upon the researches and writings of the most eminent of Germany's specialists in the science of fermentation and distillation. It covers the entire manufacture of alcohol from the raw materials to the final rectified and purified product. An illustrated circular and table of contents of this book will be sent free on application.

Electric Car Lighting*

The Development of a New Branch of Engineering

By D. F. Crawford, General Superintendent of Motive Power of the Pennsylvania Lines

It is not the scope of this paper to go into the history of car lighting and the various elements in connection with the same but merely to discuss the general proposition various systems the recent development of the same and their applicability to the various conditions to be met

Electric car lighting at this date is comparatively a new branch of engineering and its development within the past nine or ten years has removed it from the unsatisfactory experimental stage to a real and serviceable proposition There is still however, much to be desired in detail development and reduction of costs In other words the car lighting proposition is just emerging from its swaddling clothes and is a good healthy child which however needs considerable care and attention to develop it along the most satisfactory and economical lines

Electric car lighting is the last step that has been made in the lighting of passenger cars through the chain of candles kerosene acetylene and gas The reason for its adoption was primarily on account of the danger of fires with gas lighting on the occasion of wrecks Among the minor reasons for its adoption is the greater ease in controlling the amount of light desired in cars the elimination of a great percentage of heat and the furnishing of a light which would not in any way contaminate the air in the car

METHODS IN VOGUE.

At present there are four methods being developed

First —The straight storage with 30 or 60 volts This consists of storage batteries held under the cars current from which is distributed through a small panel board to the various circuits

Second —The axle generator This system is simply a straight storage system augmented by a generator driven from the car axle which by automatic means is thrown across the battery circuit when its voltage is equal or above the batteries thus charging the car en route, and (theoretically) doing away with the necessity of charging the car at terminals

Third —The head end system in which the prime mover is installed in a baggage car By this system a current is transmitted through a continuous train line to the various cars The present voltages in vogue are 60 and 110 With the 60-volt equipment as a rule each car is provided with a set of batteries by itself floating across the line With the 110-volt system one or two sets of batteries, as a rule are installed preferable one set on the observation and one set in the composite car that is, as both ends of the train

Fourth —The head-end system with the prime mover on the locomotive This system consists primarily of a steam driven generator mounted on the locomotive and furnishing current at 60 volts through train line to various cars each car being equipped with a battery

METHOD TO BE USED DETERMINED BY CONDITIONS

As yet no one of these methods has shown any decided superiority over another and the whole question is necessarily controlled by the conditions of operation to be met on the various railroads Where the lighting between charging stations is within 70 or 80 per cent of the capacity of the battery which within reason can be carried under the car and where the time of lay-over for the cars and conditions at a terminal are such that the batteries can be properly charged it is the writer's opinion that the straight storage system is the most efficient, most economical and is giving the best results from the standpoint of continuous service There are, however conditions where either the lighting load of the car is so great or the lighting hours of such duration that even with the proper terminal facilities it is impracticable to carry sufficient battery on the car to meet the demand —here we enter the sphere of axle lighting It is plainly evident then that neither the straight storage or the axle light system is capable of meeting any and all conditions of car lighting. There are various railroads that have adopted the axle lighting system as a standard equipment for all cars including passenger cars with small lighting output, while other roads find it practicable to take care of their coaches by straight storage and the dining cars business cars and postal cars with axle dynamo

The idea in the essential development of head-end system is to do away with both the straight storage and the axle light cars and to furnish current for the lights on all cars in all trains from head-end equipment a battery of medium capacity to be installed on each of the cars in order to furnish current when engines are being changed when the train is broken up by switching and in the event of the failure of the generating unit. It is doubtful if this development will ever be realized and it leaves for the engineers the choice between the two tangible systems—straight storage or axle device

THE RECENT DEVELOPMENT OF THE VARIOUS SYSTEMS AND THE ELEMENTS OF THE SAME

In any system of car lighting the element of greatest importance and the maintenance of which is rather a large per cent of the total cost is the storage battery This branch is of such importance and its development has been so great that the writer feels justified in taking up some time in going into the history operation and development.

The first practical storage battery was developed in 1860 in France, by Planté The essential scheme as outlined by Plante in the making of the battery was to take two lead plates emerge them in sulphuric acid of about 1 200 degrees specific gravity and charge and discharge them forming the active material on the lead peroxide of lead being formed on the positive plate and spongy lead on the negative plate This method is carried out to-day by the American manufacturer of storage batteries with the exception that various chemical means have been resorted to to increase the rate of the formation of the active material This process is known as a plante formation and plates made in this manner are known as plante plates

A satisfactory theory of the lead sulphuric cell is still to be developed but I will give you the following simple and generally accepted explanation of its action

We will consider that we have a glass jar filled with 1 200 degrees sulphuric acid and emerge in it two pure lead plates Now with a voltmeter across these plates we will find that there is no difference in potential Now, assume that an electric current is passed through this cell from one plate to the other calling the plate to which the positive lead is attached the positive plate and the other plate the negative This current we will assume separates the sulphuric acid H_2SO_4 into two parts or ions H and the radical SO The H ions move in the direction of the current or toward the negative plate and the SO_4 moves against the direction of the current or toward the positive plate The hydrogen will be given off as gas bubbles at the negative plate and the SO_4 radical will unite with the water at the positive plate forming sulphuric acid H_2SO_4 and liberating oxygen The oxygen attacks the positive plate forming a layer of peroxide of lead PbO_2 This process will be kept up until a certain depth of peroxide of lead is formed then the oxygen will be delivered at the positive plate in the form of gas bubbles similar to the liberation of hydrogen at the negative plate. Now if we stop the current we will find instead of zero potential between the plates that we have a potential of about 2 1 volts and that the cell is capable of discharging that is producing current in an outside circuit and will give up about 75 per cent of the energy that has been imparted to it The action in the cell on discharge is opposite to that on charge and the hydrogen which is liberated at the positive plate will reduce the peroxide PbO_2 to lead oxide which is an unstable combination and will unite with the free sulphuric acid forming lead sulphate or $PbSO_4$ while the oxygen delivered at the negative plate will form lead oxide which will unite with the sulphuric acid forming lead sulphate and we have the cell in normally discharged condition or both plates covered with lead sulphate On again charging the cell that is passing current through it from positive to negative from an outside source the same action will take place as on the original charge with the exception that at the negative plate the hydrogen instead of being liberated will unite with the lead sulphate $PbSO_4$ forming sulphuric acid and reducing the $PbSO_4$ to metallic lead which lead however is not in its original form but is in a looser allotropic form known as spongy lead We then have the plate in its normal charged condition the positive plate having a coating of PbO_2, or probably PbO_2, which is of a dark brown color and the negative plate covered with spongy lead which is light gray in color As in the first case the charge can be continued the peroxide being formed on the positive plate and the spongy lead on the negative plate until the action has reached a certain depth when as before, hydrogen will begin to be delivered at the negative plate and oxygen at the positive plate indicating the full charge of the battery

Now, with a plain lead sheet this action of charge and discharge can be continued with gradually increasing capacity of the element until the active material has reached such a depth that it will mechanically slough off at the same rate at which it is formed The capacity depends upon the amount of active material and as this amount of active material depends upon the surface exposed, the development of the plante plate has been along the lines of increasing the exposed surface of the plate and still maintaining the mechanical strength, and this has been done by the various methods of molding, cutting or rolling the sheet, so as to form ribs or grid condition to increase the ratio of the active surface to the projected surface of the plate.

A wide departure from the plante plate was made in 1878 by Faure and Metzger in Germany in the invention of what is known as the Faure' or 'pasted plate Instead of depending upon the electrochemical formation of active material on the surface of the plate Faure took a sheet of lead and punched it full of holes or in some cases the grid is cast, and the holes or recesses thus formed are pasted full of a mixture of red lead and sulphuric acid This paste or litharge, as it is called in the recesses of the plate forms a hard cement like substance, and, when the negatives and the positives are charged the plates are quickly formed into positives and negatives the positives turning into lead peroxide and the negatives into spongy lead It can be readily seen that the pasted plate can be developed into cells having considerable more capacity than the plante plate and we have the pasted plates in commercial use in connection with automobiles The pasted plate is better adapted to light rates of charge and discharge and will not stand up under heavy rates of charge and discharge as the plante plate due to the contraction and expansion of the active material which results in the breaking down of the electro-chemical contact of the active material to the supporting grid

About nine or ten years ago when the storage batteries began to be used to any extent in car lighting the battery manufacturer had, for some years been furnishing storage batteries for stationary service but unfortunately the conditions of car lighting are exceedingly hard on the storage battery, due to the constant vibration the jolting of the cars and further to the inadequate attention that can be given to the individual batteries and cells in an installation of any magnitude The normal battery used for car lighting purposes is a 280 ampere hour cell where 16 or 32 cells are used per car dependent upon whether the car is to have 30 or 60 volt lamps. There were three principal types of plates offered

First—The pasted positives and negative plate which were not found satisfactory for the service, on account of the active material being loosened up in the supporting grid and dropping to the bottom of the tanks the life of the plates being everything but satisfactory and the resultant cost of operation being high

Second—The positive plate is composed of a grid about 3/16 inch to ¼ inch thick punched full of holes about ½ inch in diameter Into these holes is pressed a button of pure lead This button is made by rolling in a spiral form a corrugated, pure lead ribbon In through coach and axle dynamo equipments, this type of plate is found to have very short life and proved to be entirely unsatisfactory for the service The manufacturer of this plate has kept pace with the development and to-day is furnishing a plante plate similar to the original with the exception that the supporting grid has been made twice the former thickness, or practically the thickness of the button, and present experience seems to indicate that this plate is far superior to the original product and will successfully meet car-lighting conditions.

Third—In the original plante battery offered for car lighting service the positive plate consisted of a pure lead grid, which had a surface developed by means of passing over it a band saw, sawing out grooves about ¼ inch or 3/16 inch deep, and a little less than 1/16 inch in width. This plate was originally pasted full of active material, which, however, fell out very rapidly, leaving only plante formation. In this condition the life of the plate was good, but the difficulties of developing sufficient surface in this method prevented its successful use, the surface being insufficient to maintain necessary active material for the capacity desired. The plante plate is now used in both negative and positive plates, the surface [illegible]

* The Yale Scientific Monthly

formed by either spinning out the lead in the ribs, by means of revolving gang knives, or by cutting and turning up the fine ribs by means of shaper knives the ribs being from 24 to 30 per inch and about 3/16 inch in depth

The plante plate was the first plate developed to successfully meet the car lighting conditions it being capable of maintaining its capacity for a big percentage of its life and being sufficiently rugged to withstand the vibration and hard knocks met with in car lighting

Recently a number of plates have been put upon the market which the manufacturer expects to meet the conditions and notably among them is a cast plante form positive plate the plate being about 7/16 inch thick and having cast through it is a series of slots less than 1/16 inch in width and about ½ inch long To date, this plate shows indications of being satisfactory for car lighting service Another type of plate recently put on the market is a cast grid and grill pate the grid being cast with openings about three inches square made of lead antimony and a pure lead grill similar to the positive plate mentioned above being burnt into these openings with sufficient allowance being made for contraction and expansion This plate is rather new and it is hard to say what the results of development along this line will bring forth The above types are most used in car lighting work but there are however numerous plates of unique design placed on the market from time to time and for which great claims have been made but which to date have not met their guarantee sufficiently to make them competitors with the plates to win service

The recent development of the Tungsten lamp for car lighting purposes and the development of the serviceable ampere hour meter may make it possible for car lighting engineers to go back to the pasted battery for the reason that

First.—The Tungsten lamp reduces the rate of discharge on a given car to about half the rate with carbon lamps and the ampere hour meter installed with 100 per cent shunt for discharge and 80 per cent shunt for charge makes it possible for the electricians at terminals to give batteries the proper charge tapering charge at completion and cutting off charge without abusing the batteries by heavy overcharge with the resultant gasing and high temperature Some of the railroads are making trials of the equipment as above mentioned but time only will tell whether or not they will be successful If the refinements in car lighting will allow the use of pasted batteries it will be advantageous both on account of the fact that the pasted batteries can be purchased for less money than the present car lighting types and are 25 to 30 per cent lighter

In regard to the Tungsten lamp itself there is no question but that this type of lamp will replace carbon lamps Its success is mainly due to the development of the so called hot circuit this being the method whereby instead of turning the current completely off from the lamp when lights are not required the lamp is merely switched from the main batteries to one or two hot circuit cells merely sufficient current being sent through the lamps to make the filament show faint red at night This arrangement prevents excessive breakage of Tungsten filament which is an unfortunate characteristic of the filament when it is cold

One of the greatest developments in car lighting work has been the containing jar The first batteries were installed in hard rubber jars with loose covers The jars were rather expensive and in shifting cars there was a continual breakage Further the slop of the acid was disastrous to the trays holding the rubber jars and the battery boxes supporting the batteries also the corroding of the terminals was excessive To do away with this trouble wooden tanks with 4-pound lead lining were developed and installed with loose covers This development proved to be very discouraging The slop of the acid rotted the tanks and the lead linings proceeded to develop sulphated spots between the wood and lead lining eventually terminating in pin holes through which the acid was lost The experience along this line was very expensive to the railroads adopting it However the advocates of the lead lining continued developments along this line and the first improvement was to cover the top of the tank with a full rubber gasket, and secure it with a wooden cover holding it in place with iron straps it being assumed that the rubber gasket pressed between the top of the lead lining and the wooden cover would sufficiently prevent slopping of acid and corrosion of terminals. This modification was an improvement but the question of leaky tanks continued and the railroad people had all they could do to keep their equipment in service.

From this stage, through a series of rapid developments, the present two-compartment lead lined tank was developed, which has proven entirely satisfactory The outside of lead tanks themselves is cleaned and covered with a coating of petrolyte, the inside of the wooden compartments is painted with acid-proof paint, and before installing the lead linings sufficient molten paraffine is poured into the wooden trap so that when the lead lining is put to place the paraf fine runs up between the lead lining and the wooden compartment completely filling this space The covers are now made of hard rubber the terminals projecting up through bushings of soft spongy rubber the covers being provided with sealing grooves to seal them with sealing compound to the lining This equipment is now standard on a number of roads and is proving to be entirely satisfactory although in engineering work there is probably nothing that is not subject to further improvement

DEVELOPMENT OF THE AXLE GENERATOR

In the installation of an axle generator on a car the engineer is met with conditions which make it anything but smooth sailing He has to drive the dynamo from an axle which does not have any constant relation to any part of the car The lateral displacement of an axle in the truck itself is about ¾ inch the vertical displacement about 2 inches Further the trucks are pivoted and can swing out of line with a car going around curves to a considerable extent Some of the first developments contemplated flexible positive drives through gears from the axle and the installation of a generator armature on the axle itself These did not meet with any great approval by the railroads first on account of the fact that the car axles have to be changed due to the wearing of the tread and the flanges and second the location of the machine made it rather inaccessible for inspection

These difficulties resulted in the development of what is known as the outside suspension which scheme with few exceptions is universally used The dynamo in this case is hung outside of the truck from bails or in a cradle and the belt is run from the generator pulley to a pulley mounted on the rough axle Belts however have a limited life and the losing of a belt en route as a rule means failure of the lights on the car or in most events of at least dim lights in service Recently a number of chain manufacturers have been offering chain drives for this service and it is hoped by the railroad people operating lighting systems that these chains will meet with success However it is too early to offer any opinion on the same The conditions of the driving axle with varying relation to the dynamo and the fact that it is absolutely impracticable to lubricate the chain puts the chain manufacturer up against a difficult proposition

The dynamo itself is not the joy of an ideal life the variations of track alignment and surface and the swinging of trucks around curves make it a hard proposition to maintain the lubrication of armature bearings and keep the oil from fields armature windings commutators and brushes The machine is necessarily devoid of any means of ventilation as dust and dirt of the right-of way must be prevented from getting into it The dynamo is used for charging batteries and lighting car and is driven by a variable speed axle and is liable to run in both directions therefore the control of this apparatus has been subject to numerous arrangements and patents To provide for the generating of current in one direction (the machine revolving in both directions) a pole changer is almost universally used This practically consists of two types first the brushes themselves are fastened to a movable brush ring and the friction of the brush revolves it in one direction or the other dependent upon the movement of the car so as to produce current in the proper direction and second a worm and cam arrangement which is in operation for the first few turns of the dynamo and changes the leads through means of a pole changer switch

The provisions for varying speed of the machine can be made in two ways First voltage regulating scheme whereby the voltage is maintained constant This would be the preferred arrangement but to date all attempts along this line have utilized instruments of such delicate construction that they have been unserviceable Second the universal scheme adopted is that of constant current. One of the first steps along this line with installation of a dynamo on the bottom of a car was the dynamo being so hung that it could be moved towards or away from the driving axle, and the varying speed of the car axle was taken care of by slippage of the belt This scheme worked out satisfactorily but practically could not be maintained The present and most universally used system is the arrangement of maintaining a constant current output from a generator by controlling the current flowing through the field One of the pioneers in this line used an ordinary rheostat two toothed wheels being mounted on the rheostat handle a dog engaging each one of them one dog to turn resistance into the rheostat and one to turn it out These dogs were made to revolve through a small arc by means of a constant running motor their contact with the respective wheels being made by means of a current solenoid This scheme for some time was the only equipment in service But in the development other schemes have been devised which are equally serviceable and have considerably less wearing parts and less liability of disarrangement. Among them is the immediate improvement of the above device in which motors dogs and cog were omitted and the controlling solenoid operates directly on the rheostat arm which swings up and down over the resistance contacts The other scheme is to provide a certain pile resistance in the field and the current solenoid brings varying pressure on a carbon pile depending upon the current and allowing more or less field excitation A rapid departure is made from the above equipments in a recent installation wherein all rheostats and regulators were omitted and the regulation is obtained by a counter E M F armature mounted on the main generator armature This counter E M F machine when the car starts up acts as an exciter its field being obtained from the battery current or in a constant direction Now as the car picks up in one direction or the other the current in the counter E M F machine will be in one direction or the other and reverse the direction of rotation of the main armature and the direction of its field excitation maintains a constant polarity As the machine picks up in speed the main contact closing the circuit of the batteries is closed and at the same time a little polarizing switch is installed whereby the excitation of the main generator is thrown across its own brushes as a shunt machine either in one direction or the other dependent upon the directions of rotation and the counter E M F machine is thrown in series with the current to the main fields and in opposite direction therefore when the car picks up speed the generator is prevented from increasing its current and voltage from the fact that the counter E M F machine also increases its voltage and cuts down the current going through the fields

In addition to the above arrangements there have been installed methods whereby machines can be set at constant current output and made to increase this output in proportion to the lighting lead thereby lighting the lamps directly and maintaining a constant charge to the batteries Developments have also been made recently along the line of cut-out switches so arranged that the machine can be cut down and battery charge ceases when the batteries have reached a predetermined voltage

The axle dynamo appeals to the car lighting engineer and in the writer's opinion if the equipment can be developed to meet the conditions and operate cheaper than the straight storage system they will be universally installed The ideal condition would be to install axle dynamos and batteries on cars so that they could run from one shopping to another with very little if any attention that is about 18 months and the regulation so perfected that no matter whether the car is in runs where very little lighting is required or in runs of continual night and lighting service that the condition would be properly matched

The event of the Tungsten lamp and the possible use of pasted batteries will tend to change some of the old theories in connection with axle dynamos The contention of the axle dynamo manufacturer has been that the installation of an axle dynamo allows the user to run his cars on 3 instead of 60 volts thereby doing away with the initial cost in the main tenance of half a set of batteries the reduced cost of the present battery and the possible use of the still cheaper pasted type of battery leaves very little if any argument in the above contention The plan of the car lighting engineers and axle generator people should be the development of a small sized machine which can be wound for either 30 or 60 volts with the same mechanical parts The 30 volt machine with 16 cells of batteries should be used on cars where the lighting needed is not over 15 amperes at 30 volts On the cars with greater lighting capacity the same machine wound for 60 volts should be used with 32 cells of batteries The above mentioned 60 volt equipment in view of the greater cost of the 30 volt machine to meet the greater lighting requirements will be as economical in operation as the 30 volt equipment but on the other hand will have more standby capacity with less lighting failures In the mean time the safest course of the car lighting engineer is to operate the straight storage system until such a time that the axle dynamo is properly developed to meet the conditions

Incense Powder.—Benzoin 250 parts cascarilla 250 parts musk 1 part sandal wood 500 parts saltpeter 100 parts vetiver root 150 parts frankincense 500 parts cinnamon 150 parts Dissolve the saltpeter in water soak the other pulverised ingredients with the solution dry the mass and re pulverise it This powder spread on a surface and moderately heated on an iron stove-lid for instance takes fire spontaneously and smoulders completely away

The Manufacture and Industrial Application of Ozone

The Possibilities of a Remarkable Gas

By Dr Oscar Linder

SINCE the discovery of ozone in 1840 by Schoenbein it has been a fascinating subject for investigation to many chemists and physicists The vast commercial possibilities of ozone have been conceived by many scientists and it is interesting to note the prophecy of Berthelot that ozone had an immense future and would ultimately work a veritable revolution in the chemical industry The scientific literature and the records of the Patent Office will bear proof of the at

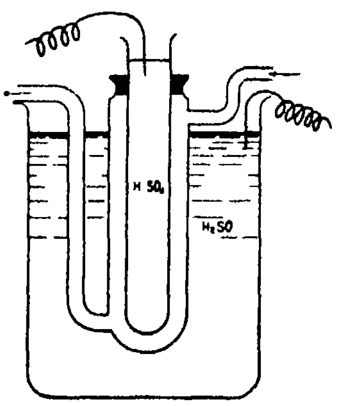

FIG 1—BERTHELOT OZONIZER

tention which has been paid to this remarkable gas by scientists throughout the world There have been more than one hundred patents issued by the United States Patent Office on methods and apparatus for producing ozone and the number of foreign patents is legion It is true that most of them are based on the original method of producing ozone by subjecting air to electrical stresses and most of the claims are but special arrangements and combination embodying this fundamental principle or means for producing the electrical stress However there are some notable exceptions such as for example methods of producing ozone by means of heat or ultra violet rays although the efficiency of these processes at the present time is too low to enable them to compete successfully with the electrical method

PROPERTIES AND OCCURRENCE

Every chemist and most laymen know that ozone is a gas with the composition O_3 and it is an allotropic modification of oxygen formed from the latter by an endothermic process According to Berthelot 29 600 calories are required to form 1 gramme molecule of ozone from oxygen Expressed in a popular way ozone may be called oxygen in a highly energized form As a gas it occurs or can be produced in greatly diluted form but it can be condensed to a deep blue liquid of a specific gravity of 1 46 which boils at —106 deg C (—159 deg F) according to some investigators and at —125 deg C (—191 deg F) according to other investigators It is very unstable in either form and upon standing decomposes slowly if greatly diluted and may do so explosively if in liquid form

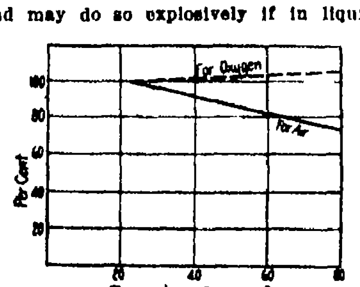

FIG 2—RELATIVE PRODUCTION OF OZONE AT DIFFERENT TEMPERATURES AS COMPARED WITH 22 DEG C (71 6 DEG F)

This decomposition increases with a rising temperature and at a temperature above 270 deg C (518 deg F) ozone cannot exist Its density as a gas is 1 66 air being 1

Ozone has a characteristic odor which is perceptible even when in extreme dilutions with air So delicate is our sense of smell to this gas that it is easily possible to detect the presence of one part ozone in about ten million parts air which would correspond to a concentration of 1/100 000 of 1 per cent It is the most powerful oxidizing agent known and will attack even when greatly diluted all oxidizable substances especially organic matter It is therefore a valuable oxidizing agent not only because of the ease of its application as a gas but also because no other elements are introduced into the reaction but oxygen

Ozone occurs in nature in the atmosphere and is supposed to be formed in small quantities through electric conditions of the atmosphere and by the action of ultra violet sun rays upon the atmospheric air The latter formation explains why it is more abundant in the higher regions where the ultra-violet rays are largely absorbed by the atmosphere The quantities in which ozone is present in the atmosphere is largely a matter of conjecture It has been given as from 0 1 to 12 parts in 1 000 000 parts by volume of air but most likely it is present, even where most abundant, in quantities of not more than 1 in 1 000 000 We are not going much wrong if we assume it to be about 1 part in 1 000 000 parts air 1/10 000 of 1 per cent or a little less than 1 milligramme per cubic meter air) The very fact that even in smaller concentrations than this its presence can be detected distinctly by our sense of smell while its detection by chemical means is at best uncertain must be taken as an indication of its importance

MANUFACTURE.

Ozone can be made in a number of different ways but the only method of commercial importance at the present time is its formation through electric stresses I might mention that a process of great interest and of commercial possibilities is the formation of ozone through the action of ultra violet rays upon air these rays being produced by means of a mercury vapor lamp inclosed in a quartz tube Another method of scientific interest is the production of ozone by means of heat in which Nernst and Clement obtained fair yields (as much as 3½ grams of ozone per kilowatt hour) by leading oxygen over incandescent bodies and cooling it immediately by liquid air F Fischer obtained equally good results by blowing air at a velocity of 70 meters per second through a slit 1 millimeter wide over a Nernst burner and then cooling it in a glass tube surrounded by water However at the present time these methods are too inefficient for commercial purposes

The apparatus designed by Berthelot a sketch of which is given in Fig 1 is the prototype of most ozonizers which are on the market at the present time Occasionally parallel plates are used in place of concentric tubes but in general there is very little difference between the different designs and makes except as to construction.

There may be either one or two layers of a dielectric material which is usually glass free from lead or mica separating two metal electrodes The latter are used mostly in the form of alluminium or tin foil pasted to the dielectric or sometimes solid metal or metal brushes which may or may not touch the dielectric The thickness of the dielectric layer is usually in the neighborhood of 3/32 inch and that of the air space about ⅛ inch but these dimensions depend of course largely on the character of the electric energy When the metal electrodes are connected to the opposite terminals of an alternating current of suitable frequency and voltage a so-called cold or silent discharge free from sparks takes place through the glass and is visible by a faint violet glow distributed evenly through the air space between the electrodes The air or oxygen to be ozonized is passed through this glow and is thereby ozonized It is not definitely known whether it is the stresses themselves which cause the ozonization of the air or whether it is due to the ultra violet rays which are generated in the air gap but the latter theory seems more probable at the present time It should be mentioned here that the use of oxygen instead of air while giving considerably higher yields and concentrations has been generally abandoned on account of the costliness of the oxygen A step-up transformer of high ratio and comparatively low current capacity constructed on the principle of potential transformer is always a part of an ozonizer except in cases where induction coils or static machines furnish the electrical energy

In order to understand the action of an ozonizer it is necessary to first dwell upon the influence of voltage heat and moisture on the generation of this gas and upon the relationship between yield and concentration

The amount of ozone which can be generated in an ozonizer of the Berthelot type is theoretically in direct proportion to the voltage of the discharge per unit of air ozonized This would be true in practice if it were not for the destructive action of heat on ozone There is a considerable amount of heat formed in the so-called cold or silent discharge and the heat thus generated increases of course as the square of the current of the discharge In using a high wattage of electric discharge per unit of air ozonized a condition which is necessary in order to obtain the high yields and concentrations required for industrial purposes it is desirable therefore to use as high a voltage and as low a current as feasible Most failures in ozone generators are due to insufficient understanding of this principle the natural

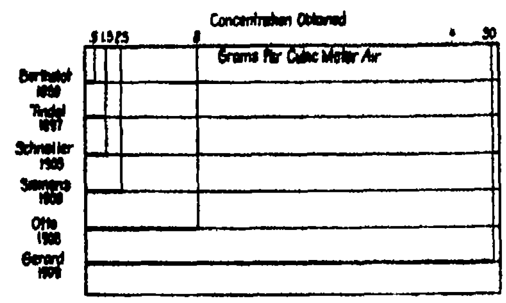

FIG 3—INCREASE IN 20 YEARS IN CONCENTRATION OF OZONIZED AIR

tendency of designers being to use as low a potential as possible There is no good reason for employing low voltages and it is now proven that contrary to former belief the formation of ozone is not limited to certain voltages or frequencies It is only at about 8 000 to 10 000 volts that the process of ozonization becomes economical and apparatus employing voltage below that are hopelessly low in efficiency for all purposes where both high yields and concentrations are required In former years limited knowledge of high potential transformers and other alternating current machinery made it necessary to use low voltages but at the present time the design and manufacture of small and efficient apparatus is of this kind affords no difficulties and there is therefore no necessity of restricting the voltage employed Voltages as high as 40 000 volts are now used and the most successful ozonizers are those which employ high voltages

The effect of heat on the formation of ozone is illustrated in the diagram shown in Fig 2 which is taken from L Gerard's treatise on ozone in the August number of the Proceedings of the Societe Belge d Electricians 1909 from which you can see that the production rapidly diminishes as the temperature increases After 80 deg C (177 deg F) it falls off still more rapidly and at 270 deg C (518 deg F) it is 0 The importance of keeping the electrodes as well as the air to be treated cool can readily be grasped from this diagram

The very best designed ozonizers still generate a sufficient amount of heat so that for commercial yields and concentrations it becomes necessary to resort to

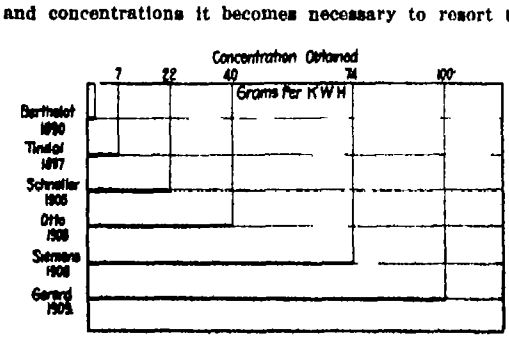

FIG 4—INCREASE IN 20 YEARS IN THE YIELD OF AN OZONIZER

artificial cooling of the electrodes or of the air to be ozonized Some designers have even resorted to refrigeration of the air before ozonization and some very good results have been obtained thus but it should be said that refrigeration is not necessary in small apparatus if sufficiently high voltages are used although for low voltage discharges it is perhaps the only means of obtaining anywhere near commercial yields

The concentration of ozonized air is the amount of ozone expressed in grams contained in one cubic meter air, and is a very important factor in all processes in which ozone is used The yield of an ozonizer is usually expressed by giving the amount of ozone generated in grams per kilowatt hour electric energy consumed. The latter includes the transformer losses

* Paper read at the ... of the American ... of Chem... Engineers at the meeting held June 24th 1910 at Niagara Falls N Y

but no other auxiliary apparatus Much progress has been made during the last 20 years in both concentrations and yields obtained as shown in Figs 3 and 4, which are taken from Gerard's above noted treatise You will notice that concentrations as high as 30 grammes per cubic meter air which would correspond to two per cent by volume and yields as high as 100 grammes per kilowatt hour have been obtained Very recently even higher yields have been achieved in an experimental plant built on the Steynis refrigerating system which is reported to have given never less than 105 grammes and sometimes as high as 250 grammes of ozone per kilowatt hour at a concentration of about 4 grammes

Unfortunately an ozonizer is in its action similar to a storage battery and it is at the present time impossible to obtain the highest concentration at the greatest efficiency and an increase in the concentration will bring with it a decrease in the yield or *vice versa*. This is easily understood when the heating effect of the discharge is considered In running an ozonizer at a high concentration the wattage of the electrical discharge per unit of air to be ozonized must be high and this necessitates a slow rate of flow of the air to be ozonized or a high density of discharge per unit of electrode surface Both these conditions favor excessive heating of the air during ozonization and this we have seen is unfavorable to a large yield On the other hand in running an ozonizer at a high yield the most effective cooling of the electrodes is necessary and can be best obtained by circulating through the electric glow a large volume of air resulting of course in lowered concentration (see Fig 5) It is evident that this relation between concentration and yield being due to the heating effect of the discharge will be all the more favorable from a commercial standpoint the higher the voltage employed

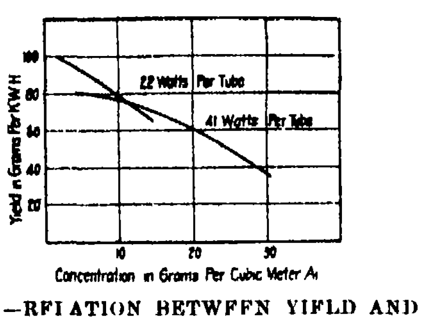

FIG 5—RELATION BETWEEN YIELD AND CONCENTRATION OF GERARD OZONIZER

The density and discharge per unit electrode surface is a factor depending largely on the design of the apparatus and on the voltage and rate of flow of the air through the apparatus As a general rule it is considered good practice not to exceed 0 4 watt per square centimeter electrode surface

The effect of humidity of the atmosphere on the production of ozone is shown in Fig 6 The presence in the air to be ozonized of water vapor so greatly reduces the production of ozone that for all commercial concentrations except for ventilation it is necessary to dry the air before ozonizing it This practice is followed in almost all instances and is usually accomplished by passing the air through a tank containing lime before passing it through the ozonizer or in large plants by refrigeration

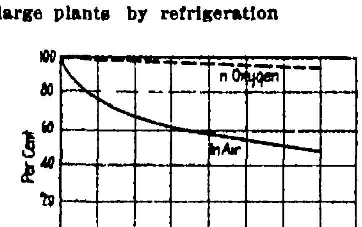

FIG 6—RELATIVE PRODUCTION OF OZONE AS A FUNCTION OF HUMIDITY

It must be understood that where very low concentrations only are required such as for ventilating cooling and drying of the air In a well designed apparatus of this kind sufficient cooling is accomplished preferably by the artificial circulation of the air set up and the reduced production of ozone in the presence of such water vapor can be taken care of by making the apparatus adjustable

In subjecting air or oxygen to the effect of electric stresses, it is well known that some other products are formed besides ozone. If water vapor is present in the air or oxygen, there may be some hydrogen peroxide formed. However, the drying of the air before ozonization does away with this possibility In small ozonizers used for ventilating purposes in which it is not customary to dry the air, the amount of hydrogen peroxide formed is so small and the dilution so great that its presence can be disregarded, especially considering the great similarity in action between hydrogen peroxide and ozone

Besides hydrogen peroxide there is always formed a more or less small amount of the oxides of nitrogen Their presence in the ozonized air is highly undesirable and should be carefully avoided The formation of these oxides is favored by heat sparks dust and dirt, and it is therefore important in the construction of ozonizers not only to provide sufficient cooling but also to prevent the formation of disruptive discharges or sparks in place of the cold or silent discharge during the operation of the apparatus The formation of sparks is favored by the accumulation of dust and dirt in the air space therefore in the design of ozonizers it is very important that particular attention be paid to the necessity of keeping the air space clean and free from accumulation of dust and dirt The amount of nitrous oxides formed is as a rule very small In well designed ozonizors there should not be more than one or two per cent of nitrous oxides formed figured on the amount of ozone generated In poorly designed apparatus the amount of nitrous oxides formed may run up to five or ten times this amount

During ozonization the air to be treated must be kept in positive motion a fan blower or air pump is therefore a necessary accessory of every well designed ozonizer

In regard to the quantitative determination of ozone it should be said that most of the figures which we find in the literature up to about ten years ago are unreliable owing to defective methods At the present time the determination of ozone in the higher concentration does not afford any difficulties but in low concentrations such as in the atmospheric air accurate determinations are even now impossible For industrial use the method now considered standard is the absorption of ozone by means of a neutral potassium iodide solution The iodine set free by the ozone is titrated after acidifying in the regular way by means of sodium thiosulphate and starch The hydrogen peroxide which may be found in the presence of vapor in the air to be ozonized is best eliminated by passing the ozonized air over finely divided chromic acid crystals before passing it through potassium iodide solution For very small concentrations manganese chloride paper in conjunction with Quajak tincture or Thallium suboxide as recommended by Engler and Wild and also the well known tetra base paper are giving fair comparativ results They are not however accurate enough for determining quantitatively the amount of ozone in the atmospheric air

It is not the intention of this paper to go into details as regards various apparatus for producing ozone as there are a number of treatises available where this information can be obtained For example the book on ozone by Henry Lecoux the paper on ozone by Leon Gerard in the August number of the Proceedings of the Société d Electriciens 1909 the various papers by Ehrlwein F Fischer Warburg and many others some of which I mention in this paper Most plants where a large amount of ozone is consumed have been designed specially to suit the conditions of one particular problem Therefore there is no such thing as standardization in this line and the number of designs so far is nearly as great as the number of installations

The first ozonizer constructed to meet with some success was that of Berthelot in 1899 a sketch of which is given in Fig 1 The general principle of this apparatus has not been changed to any great extent by later investigators although changes in details of construction and the progress in our knowledge of alternating current machinery made it possible for later designers to greatly increase its efficiency

The best known of the ozonizors of recent date working on the Berthelot principle is that designed by the engineers of the Siemens & Halske Co whose comprehensive investigations and publications have done much to bring the subject to the attention of the technical world A still more recent design and and which has achieved considerable success is that of Gerard a sketch of which is given in Fig 7

INDUSTRIAL APPLICATION

The industrial application of ozone has been delayed greatly in the past by unusual requirements set up by the manufacturers of such apparatus in regard to the nature of the electric current supply Until comparatively recently it was necessary to use static machines or induction coils run by primary batteries in order to obtain a discharge of the characteristics recommended by the manufacturers and even today the use of interrupted direct current or of alternating current of frequencies not met with in practice are prescribed for some apparatus It is no wonder that under such conditions the use of ozonizers has made slow progress but fortunately it has been found that the regular alternating current of commercial frequencies can be used just as well and in most cases to better advantage, than many special forms of electrical energy recommended in the past Thus it is now possible to purchase ozonizers operating from alternating lighting circuits without further electrical apparatus than a transformer In places where direct current only is available we can convert it into an alternating current of the desired frequency by means of a small and inexpensive converter several types of which are now on the market for that purpose Small ozonizers for ventilating purposes are even made so complete and compact that they can be connected to any electric light socket by means of a screw plug and cord and they can be obtained for any commercial voltage either alternating or direct current.

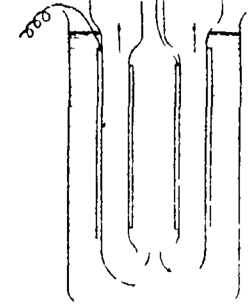

FIG 7—GERARD OZONIZER

Water Purification—The subject of water purification by means of ozone has been so extensively treated and discussed in the past that it is not necessary to go into details The success of this method of water purification has been definitely proven and it has been found that in large installations it is not only much safer and more effective but also cheaper than quartz filtration and requires much less space Large installations for water purification are as a rule designed specially to suit the requirements of one particular problem therefore the subject can not well be treated generally with other uses of ozone

The bactericidal properties of ozone since having been studied and proven by Froehlich and Chimuller have perhaps been more frequently investigated than any other of its properties and the fact that bacteriologists like Pasteur Roux and Koch have endorsed them has left no further doubt in the minds of the most skeptical persons Ozone oxidizes the impurities in water and renders them harmless It clears dirty water and still leaves no compounds harmful to the health or disagreeable to the taste This purification is accompanied by a distinct phosphorescence of the water In cases where muddy appearance is largely due to substances of mineral origin it is customary to partially clear the water by means of a pressure filter before ozonization At different times it is customary to use about twice as much ozone as is found necessary to thoroughly purify an average sample of the water in the laboratory The concentrations used for water purification are high and range from 5 to 12 grams of ozone per cubic meter (35 3 cubic feet) of air according to the quality of water The amount of ozone required for purifying one cubic meter of water also varies greatly according to the quality of the water but may be given as from 0 5 gramme to 10 grammes ozone per cubic meter of water The above figures represent about the limits ever used for purifying water of any kind

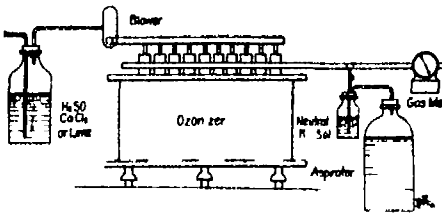

FIG 8—APPARATUS FOR USE IN THE APPLICATION OF OZONE

Owing to the low solubility of ozone in water (it is given as from 5 to 10 parts in 1 000 parts water) a very intimate contact between ozonized air and water is necessary and this is usually accomplished in towers constructed on the principle of the absorbing tower or by sprays and injectors

There seems to be no close agreement between the figures published about the cost of operation of the water purifying plants now in operation but a perusal of the data available would show the cost of purifying including interest depreciation and maintenance as being from 0 1 to 0 4 cent per cubic meter or from $3 80 to $15 per million gallons according to the quality of the water to be purified

Ventilation—One of the newest fields for the application of ozone is in the ventilation of rooms and buildings Good ventilation is being appreciated more and more because of the physical comfort which

it affords as well as because of its therapeutic and hygienic importance In all modern buildings, theaters passenger boats hotels etc, a ventilating system is an important part of the equipment and even in places the very name of which is associated with bad air such as street cars sleeping cars tunnels etc the feasibility of supplying good air is being seriously studied Up to the present time the problems of ventilation have mostly been categorically solved by heating or cooling the air to the proper temperature and in some few cases by filtering it through a sheet of water or a solid filter Recently however the demand has arisen to improve the air by charging it with ozone to a concentration corresponding to the normal percentage found in places noted for the purity and freshness of the atmosphere

It has been found and demonstrated that the presence of ozone in air in small quantities has a beneficial physiological action It gives it a pleasant and cheerful effect which is not noticed in air free from ozone It stimulates the appetite and produces sound sleep Its action has been compared with the effect of moderate physical exercises upon the general condition of body and mind Physical examinations of people working in places which are supplied with poor air have disclosed a decided gain in weight and chest measure after ozonizing their air supply for some weeks

Ozone is now considered a necessary constituent of good atmospheric air It is well known that air in cities and in all well populated places is depleted of or entirely free from ozone owing to the abundance of oxidizable organic matter in such districts The absence of such floating matter in the open country and especially in the mountains and on the sea is held accountable for the presence of ozone and for the general healthiness at such places

The question how to improve the air in cities and in closed places where people congregate is a problem which is just now receiving some serious attention for the reason that by far the largest percentage of deaths among the adults in cities is due to diseases resulting from bad air Perhaps the greatest destination of ozonizers is in the field of improving general air conditions for the powerful oxidizing properties of ozone can be put to a particularly practical use for purifying and deodorizing air Indeed it has been found that foul gases organic matter floating in the air offensive odors and everything else which is commonly called air sewage is thoroughly oxydized and destroyed by ozone Ozone in high concentration will kill any germ known to science In concentration for breathing purposes its action is different It is well known that this matter which we have defined as air sewage is a specially attractive ground for bacteria, miasmata and other animal and plant life of the lowest order which thrive in cities and congested districts In such small concentrations as ozone is employed in ventilation its beneficial action is probably its destruction of organic purposes it is usually unnecessary to employ artificial matter in the air rather than the direct destruction of bacteria which has sometimes been accredited to it It has not been proven that ozone when diluted to the extent of one part in one million parts of air can act directly as a bactericide but it is an established fact that even in such dilutions it acts as a deodorizer and destroyer of the food and favorite surroundings of the bacteria thus depriving them of the conditions favorable to their propagation So energetic is the action of ozone on such undesirable matter that the presence in the air of ozone can be taken as an indication of the purity of the air

Ozonizers made specially for ventilating purposes are now on the market and are made either of portable or stationary type There are several systems manufactured in this country and in Europe the latest one on the domestic market is made either for alternating or direct current and in various sizes to suit the requirements of the air space to be taken care of and is portable self-contained and adjustable The general plan of these machines is to draw in the air to be ozonized and subject it to electrical stresses by passing it through an air gap in which a silent electric discharge takes place and then discharge it immediately to the outside air

The cost of operation of such ozonizers is as a rule very low The consumption of electric current is about 65 watts for circulating and ozonizing 10 000 to 15 000 cubic feet of air per hour The concentration is of course very small and does not greatly exceed that found in the best outdoor atmosphere It should be mentioned here that a common mistake made in the installation of ozonizers for ventilating purposes is that too high a concentration of ozone for breathing purposes is produced An excess of ozone in the air is unpleasant to many people and while it cannot be considered dangerous still there is a possibility of producing temporary discomfort. The concentration best adapted for breathing purposes has been a subject of much discussion and it has been variously given as from 0 001 to 0.5 grammes per cubic meter air For direct breathing a concentration of 0 5 gramme is much too high and would be extremely unpleasant even for only a few minutes. The figure that has been best agreed upon is a concentration just a trifle higher than the natural concentration in the atmospheric air say about two parts ozone in 1 100 000 parts of air or about 0 0012 grammes ozone per cubic meter air A popular instruction for the use of such ozonizers is that there should be enough ozone in the air that its odor is just perceivable at all times Ozonizers giving higher concentrations than 0 01 gram cannot be considered safe, and in using such apparatus particular pains must be taken to have the concentration properly reduced by diffusion

While one is inclined to regard these ozonizers skeptically at first still their benefits in every day life have been proven and demonstrated in many cases by medical authorities As a general means for improving the air and as a deodorizer ozonized air has found no rival and is bound to come into very general use Numerous houses hotels schools, theaters and restaurants and especially abroad the leading establishments of this kind have been equipped with them and the reports on their effectiveness are generally very gratifying

Miscellaneous Applications—The industrial applications other than for water purification and ventilation are manifold What I have said about manufacture ventilation and water purification will give you a fair idea of the possibilities along different lines and I have perhaps treated these two applications at greater length than their relation to chemical engineering demands

For reasons previously explained the use of ozone as an oxidizing agent in purely chemical industries has not yet been recognized to any great extent. Since however it has been possible to obtain concentrations up to 30 grammes of ozone per cubic meter of air which corresponds to two per cent of volume by means of a comparatively simple apparatus many possibilities present themselves of using ozonized air for oxidization process especially in cases where it is desirable that no foreign elemeht be introduced into the reaction

By virtue of its gaseous condition and its powerful oxidizing qualities ozone is an ideal gas for sterilizing and disinfecting purposes Like all strong oxidizers ozone is destructive to animal and vegetable life of the lowest order while to animals of higher order and to human beings it is comparatively harmless There are several installations that are being experimented with in order to test the efficiency of ozone as a disinfectant one being for example at the quarantine station at New York and another one at the Pittsburgh Homeopathic Hospital Judging from the results obtained in sterilizing rooms bandages laundry and surgical instruments in hospitals it is believed that ozone will ultimately supplant formaldehyde in disinfecting rooms and buildings The concentration used for disinfecting and sterilizing purposes is of course rather high and should not be less than 5 grams and preferably as high as 10 grams per cubic meter air The sterilization of sewage is a problem which we will be confronted with in the near future in order to avoid the increasing pollution of our rivers and lakes and will be a very fruitful subject for ozone some day and one in which it will have to show its full worth Very considerable concentrations are required for this purpose and 10 to 20 grammes per cubic meter air will be none too high

The uses of ozonized air in medicine are many but it is not within the scope of this paper to discuss them Let it be mentioned that it has been used successfully for inhalation in cases of anemia nervousness insomnia and pulmonary diseases or for local application in the treatment of skin diseases can cerous growths in obstetrics etc

One of the largest fields for ozone in the future is the preservation of food products Experiments have shown that milk cream and butter can be completely sterilized and therefore kept from fermentation and souring for a considerable period of time eggs when stored in an atmosphere of ozonized air will keep for months without apparent change the effect on fruit is still more striking as ozone prevents the molding which starts on the outside of the skin In storing meat products it has been found that refrigeration is greatly helped if the air in the storage rooms is ozonized and that the temperature of the refrigerating room or chamber can be considerably higher in the presence of ozonised air than under ordinary conditions As a preservative, ozone is also destined to meet with considerable use, supplanting drugs, sugar and sterilization by heat.

The apparatus necessary in the applications of ozone is very simple It is illustrated in Fig. 8 and consists of the drying bottle or tank, containing sulphuric acid calcium chloride or lime the fan, blower, or air pump necessary to circulate the air through the ozoniser and the ozonizer proper containing the step-up transformer For experimental purposes it is usual to have a rough testing outfit in connection with the apparatus, consisting of an absorbing bottle for the potassium iodide solution, an aspirator to draw in from the main tube and measure the volume of air passing through the absorbing solution, and a gas meter in the main line, by means of which the total volume of air ozonized can be measured.

Considerable success has been achieved by the use of ozonized air in order to prevent the growth of parasites, as for example, in the storage of flour and flour products, to prevent molding It has also been applied in many cases, especially in England and Belgium, to the fermenting cellars of breweries, where it prevents the growth of parasites and still has no retarding effect on the fermenting process The number of living bacteria in those cellars is said to be thereby also greatly reduced, and it is generally found that those which are not directly killed are not capable of reproduction

Concentration of about 0 5 gramme ozone per cubic meter air is usually adapted for this purpose Besides this a number of breweries have adopted the ozone system for the purification of their water

In the case of the manufacture of wines and liquors ozone is being used to a large extent in France for the purpose of destroying the empyreumatical odor and oxidizing the fusel oils in products which have not been sufficiently aged The action of ozone in this case is said to be identical to the action of aging and it is reported that wines and liquors are produced in France in from three to twelve months which cannot be distinguished from similar products which have been aging for from two to ten years Ozonized air is also largely used for sterilizing casks and other implements used by producers of wines and liquors

The bleaching and deodorizing properties of ozone have been recognized early and are now being utilized to a considerable extent in the case of fats greases, and oils of mineral, vegetable and animal origin Vegetable oils for example are not only bleached and discolored but also thickened and in the case of animal products like tallow grease and fats, ozone has been found a valuable means of improving appearance and quality Rancid and other offensive odors can be entirely removed and it is possible in this way to considerably reduce the amount of waste

In the case of sugars, as well as flour and starch ozonized air has been found to accomplish bleaching very satisfactorily Its bleaching effect is superior to even that of chlorine and is all the more striking as it not only bleaches but destroys diseased parts and kills parasites which feed upon such products There are hundreds of other applications of ozone in bleaching such as for example delicate processes like bleaching of ostrich feathers and fine fabrics In ordinary laundry work ozone surpasses the effect of bleaching chemicals and has the additional advantage of sterilizing the fabrics without injuring the strength and flexibility of the fiber such as the bleaching agents generally used for this purpose do The bleaching of wood pulp is also one of the future fields for ozone As to the concentration of ozonized air which is employed for bleaching it is evident that it should be as high as possible and an average of 8 grammes per cubic meter air is none too high

There are a number of purely chemical uses for ozone, and it is safe to predict that as an oxidizing agent it will come into much more general use in chemical manufacturing and research work than it is at present. As an example I call attention to the use of ozone in the production of artificial camphor in the synthesis of rubber and the large field it will have in the future in the manufacture of perfumes

The metallurgical industry has started to make quite an extensive use of ozone in the cyanide process of extracting gold and it is claimed that the yield has been increased from 60 per cent to over 90 per cent by means of ozonized air

A field for ozone which has not as yet been exploited but which is bound to become important in the future is the sterilization of the water for refrigeration. Ice made from water which has previously been purified with ozone is perfectly clear and sterile, and will ultimately fill a long felt want in this direction

As a deodorizer there is no substance which can anywhere equal ozone and it is possible by means of it to remove in an incredibly short time offensive odors in storage rooms, glue and leather factories, and in other establishments noted for their disagreeable odors.

The outline which I have given here of the accomplishments and possibilities in this new field should serve the purpose of calling attention to and awakening an interest in a remarkable product which for general usefulness is surpassed by very few of the thousands of substances known to chemistry There is no special branch of the chemical industry where ozone cannot in some manner or other fill a want, and I believe that there are few, if any members of this Institute present who will not find it to the interest of the industry they represent to further investigate the subject.

The Generation of Power*

The Enormous Development of the Energy Stored by Nature

By D. S. Jacobus, E.D.

No art has developed within the last few years at a more rapid pace than that of the generation of power. This development has been in the line both of an enormous increase in the amount of power produced and in the economy with which it is generated. With this have come developments in the electrical field, and so closely are the two related that the unit of measurement of efficiency of our power plants is usually expressed electrically, that is, in the cost required to generate one kilowatt of electrical energy per hour, or the amount of fuel or its equivalent heat value required to generate a kilowatt hour.

The great advance in artificial illumination brought about by the electric light, the establishment and extension of trolley lines for city and interurban service, and the distribution of power to both small and large consumers have heavily taxed the resources of our central power plants, which have been continually increased in capacity to meet the demands. So rapid has been the advance that what was the best practice but a few years ago is in most cases not the best practice of to-day, and it is no rare occurrence to see equipments which were up to date less than ten years ago replaced by something better. The development of the steam turbine has had much to do with this—a development which has proceeded so rapidly that it must be regarded as one of the marvels of engineering.

Steam is to-day the ruling power. Hand in hand with steam come the gas-engine and hydraulic power developments. Each has its own particular field, and any individual case must be considered by itself before it is possible to say which form of power will be the most economical. Of these three methods of generating power the hydraulic surely has the advantage as far as the conservation of our natural resources is concerned, but history has shown that the development of most water powers is simply a preliminary step to the installation of an auxiliary steam plant to insure continuity of service, and in many cases the power demands become such that the steam plant is eventually the more important of the two. What follows will bear more especially on the production of power by steam.

We often hear the cry that we are a wasteful people, and that we should save our coal deposits and make more use of such natural powers as the wind and the waves. These methods of producing power, especially in the case of the wind, have filled particular needs, but as a means of generating the large quantities of power now used for industrial purposes they would be completely inadequate. For example, let us consider the power generated by a single steam turbine of 20 000 kilowatts capacity. To produce this power with windmills each having wheels 25 feet in diameter, and with a wind velocity of 20 miles per hour, we would need over 6 000 windmills, and if the mills were placed 50 feet apart they would form a line about 60 miles long.

Again, let us compare the power obtained from the steam turbine with that available from a wave motor. If we should construct a wave motor which would convert half of the total energy contained in the waves into electrical current, and which would be operated by a continuous series of waves 200 feet long and 4 feet high, it would have to extend along the coast for a distance of about a mile and a third to give as much power as the single steam turbine. The cumbersomeness and cost of constructing such a wave motor would render it impracticable, whereas for certain uses where smaller amounts of power are needed a wave motor might be developed to serve the purpose.

Let us consider animal power. A horse develops, say, three-quarters of a steam-engine horse-power under favorable conditions, which means that about 35,000 horses would be required to do the work of the single 20,000-kilowatt steam turbine.

The consideration of the subject from a theoretical standpoint is most interesting. The steam engine is handicapped in its efficiency as compared with the gas engine by the lower initial temperature of the working fluid in the cylinder, whereas the gas engine is handicapped as compared with the steam engine by not being able to make use of a low temperature at the end of the cycle. In a steam engine a great part of the work is done by the steam at a pressure below the atmosphere, every degree that the condensing water is lowered being available for increasing the work and representing the lower limit of temperature. The steam turbine is especially adaptable for utilizing the low temperature at the end of the cycle. In a gas engine the lower limit of temperature is that of the hot gases at the end of expansion, a temperature usually higher than the initial temperature of the working fluid in a steam engine.

The question is often asked why a good arrangement could not be obtained by combining a low pressure steam turbine and a gas engine so as to secure the benefits of the high initial temperature in the gas engine and the low final temperature in the steam engine. On working out an actual example, however, it will be found that the work of the steam turbine would be comparatively small, amounting to less than 10 per cent of that of the gas engine, so that the installation of the steam turbine would not as a rule increase the capacity or efficiency enough to warrant the additional expense and complication of the plant.

Many so-called new cycles for the production of power have been brought out from time to time. In most cases these cycles serve as an illustration of the old adage that a little knowledge is a dangerous thing. The inventors often work out pages of thermodynamic formulæ to uphold their views. In other cases the problem is dealt with in broad generalities, heat units being handled as if they were packages that could be moved at will from shelf to shelf, and so made to pass from one part of the apparatus to the other without loss, no consideration being given to the amount of surface required to effect the transmission or to the radiation losses. In some cases heat is assumed to be transferred from one part of the cycle to the other, no proof being offered that the interchange will be possible, that is, from a hotter to a colder medium. Still other inventors actually build machines only to find that this is the most expensive way of becoming convinced that they are mistaken. I have had to examine many such schemes, and in most cases it could be readily shown that the cycle was at variance with the well known laws. Cycles that do not conflict with the laws can usually be shown to be impracticable when the sizes of the parts necessary for an actual machine are computed and the radiation losses allowed for. If we could but find a way of disposing of heat at a temperature lower than that of the surrounding objects, we could utilize all of the heat of the ocean or the atmosphere to develop power. Many of the schemes advanced in the so-called new cycles are equivalent to this, and the inventors have wasted their energies in striving for the impossible.

Much depends on the load curve of a power plant in obtaining economy. If a continuous uniform load could be carried, many of the vexing problems which confront the power plant engineer would be eliminated. It is difficult to carry economically enough reserve capacity to meet the daily peaks in the load. Then again there are exceptional peaks which occur only at rare intervals, so that a considerable percentage of the available power may be developed only for a few hours every month, or for that matter for a few hours every year. Modern practice leads more and more to developing higher ratings from boilers during such intervals, and a boiler should be used which under proper operating conditions may be driven to a capacity that is limited only by the amount of coal which can be burned in the furnace. Again, it is desirable to use boilers that may be cut into the line quickly, either from banked fires or starting from a cold state.

The practice in this respect is exemplified by considering the installations of the Commonwealth Edison Company at Chicago, where the first 5 000 kilowatt turbines erected in this country were installed. This was in 1903, and eight boilers, each having about 5 000 square feet of heating surface, were supplied for running a turbine. The maximum rating for these turbines was 7 500 kilowatts. Later on 12 000 kilowatt maximum rating turbines were installed, each with eight boilers of the same size as provided for the 5 000-kilowatt machines. Still later machines of 14 000 kilowatt maximum were run with the same size and number of boilers as the original machines of 7 500 kilowatt maximum.

The steam pressure in power plants of this country is usually about 185 pounds to 200 pounds per square inch, and about 150 deg. of superheat is carried. The economy of superheat in this work is well established and represents the best practice.

The steam turbine is becoming more and more the standard for large power-plant work, both on account of its fuel economy and the low cost of attendance. The most economical fuel consumption under operating conditions that has so far been published was obtained in a test with piston engines, where a kilowatt hour was turned out of the station for each 25 000 B.t.u. contained in the fuel. The station referred to is the Redondo plant of the Pacific Light and Power Company of California, and the results of the test, at which I was fortunate enough to be present, were given by the designer of the plant in a paper published in the Transactions of the American Society of Mechanical Engineers for 1908. The fuel was California crude oil. The load curve had two high peaks, and the entire plant was shut down during a lay-over period of four and a half hours per day. The 25 000 B.t.u. represent the heat of combustion of the oil used per kilowatt hour net electrical output for the entire fifteen-day period during which the test was run. It is a fact worthy of note that this result approaches that to be expected for the plant economy of large gas engines for the class of service considered, where the power is variable and reductions must necessarily be made for all the auxiliaries, etc.

While no results for plant economy as good as the above have been published for steam turbines, it is only fair to say that the figures for steam consumption for turbines show that better than this economy can be obtained under uniform load conditions. When it comes to plant economy so much depends on the load conditions that it is hard to compare one plant directly with another.

We have in this country many large power plants. In New York we have the Edison Waterside stations and the Interborough station; in Boston the Boston Edison Company's station; and in Chicago the Commonwealth Edison Company's stations, two of which, built near each other at Fisk and at Quarry Streets, have an aggregate maximum capacity of over 200 000 kilowatts. *It is noteworthy that the first 5 000 kilowatt turbines installed in this country*, which have already been referred to, were placed in the Fisk Street station about seven years ago. The rapid development in the art is exemplified by the fact that these turbines are now replaced by others, although at the time they were installed they represented the latest advance in power plant practice.

The growth in the consumption of power has been so enormous that the question is often asked, Where will it stop? What is a luxury to-day becomes a necessity to-morrow. Where our grandfathers used the tallow dip and oil lamps, we must now have a flood of light rivaling that of the sun itself. Our streets are illuminated in a way that our forefathers would have considered impossible, and no one would wish to go back to the darkness that would tempt the highwayman and render travel difficult. Ventilating fans are now regarded as a necessity, and electrical current is used for a number of household purposes. We could not indeed go back to the old days without giving up many comforts. But where will this great increase in the demands on nature's coal pile land us? This we will have to leave to others to answer. Let us stop for a moment, however, and compare what we are doing with that great silent source of heat and power, sunshine. The sun shining on the world for a single minute imparts as much heat as that contained in all the coal and oil produced in our country in a year, and when we make this comparison we cannot help but appreciate the littleness of our endeavors and have confidence in the great recuperating powers of nature.

Economy in Meat Production

At a recent meeting of the French Agricultural Society a paper was read by Messrs. Gouin and Andouard, discussing the influence of the age at which cattle are slaughtered upon the production of meat. It has been stated by some that the present scarcity of meat in France is due to the method in vogue of slaughtering animals before they have reached complete development. The authors consider that this is an error, and that stock should be utilized as soon as the flesh has attained its value as meat for the table, this being to the advantage both of producer and consumer. The total amount of hay fed to three animals up to the age of 3½ years is 33 long tons. This would suffice for seven animals up to the end of the second year. But the yield in meat from the seven young animals is 10 per cent in excess of that from the three adults. Thus with the same amount of food material the stock raiser can put much larger quantities of meat on the market by rapidly renewing his stock.

The Bergen-Christiania Railway

A Recently Completed Scandinavian Line

By the English Correspondent of the Scientific American

One of the most important railway enterprises which has been completed in Europe within recent years is the trunk standard gage line that has been recently opened across the Scandinavian peninsula for the purpose of providing direct communication between Bergen on the Atlantic seaboard with Christiania. The necessity for such a link has been sorely experienced for many years past, but the engineering difficulties confronting the scheme were of such a stupendous character as to prevent its earlier realization.

The line was first projected in 1870 and was estimated to be about 320 miles in length. It was realized from the first that construction would be difficult inasmuch as the mountains to be negotiated rise very abruptly from the sea and the interior plateau is storm swept throughout the whole year. However two engineers were selected to ascertain its feasibility. Their report was of such a favorable nature as to induce the authorities to sanction the first part of the scheme which entailed the building of a meter gage line from the sea to Vossangen at the foot of the mountain range a distance of about 67½ miles. The work was commenced forthwith, and was opened for traffic in 1883.

The extension of the line eastward was not abandoned but the main difficulty was to find an easy passage through the mountains. This was a difficult matter as the range is so broken up. The engineers made several preliminary surveys and elaborated several routes but in any case extensive tunneling would be requisite. These preparations occupied eleven years and it was not until 1894 that the actual extension was sanctioned. Even then the authorities only decided to proceed as far as Taugevandet 114 miles from Bergen leaving the further extension open for the time being.

The engineers pointed out that owing to the range dropping so precipitously into the sea with an absence of wide valleys the line would have to rise to a great altitude to secure a favorable grade. They also emphasized the fact that owing to the exposed nature of the interior table land rain and snow would also remain a serious problem. The snow in particular was a sore question and to gather reliable data concerning its fall drift, and so forth several meteorological stations were set up in 1884 and daily observations made. These revealed a rather remarkable state of affairs it being found that snow fell every month during the year and that the average fall during the winter was 11 feet deep. Its movement was also extraordinary owing to the severity of the winds which caught the soft dry snow and piled it into drifts which formed as much as 16½ feet deep. Even in the month of August in the sheltered places, drifts were found over 3 000 feet in length by 5 feet deep.

These observations sufficed to demonstrate that constructional work would be arduous and difficult and also that extreme precautions would have to be observed to keep the line open and to mitigate the evil consequences of the drifting movement by means of extensive defenses in the form of wooden screens. In all nine routes were drawn up and submitted to Parliament. The outstanding feature of these routes was the means of penetrating the range from the coast side. A tunnel could not be avoided, and the most feasible route was one involving the boring of twelve tunnels aggregating 11¼ miles in length in the total distance of 47¼ miles through the range from Voss to the summit of Taugevandet. The most formidable was the Gravehals tunnel, 17,490 feet in length. The steep grades and sharp curves which were necessary to preserve alignment were also vital factors.

The government, however accepted the Gravehals tunnel route. After leaving Voss the line commences its ascent of the range immediately, rising from 150 feet above sea level to the Taugevandet summit at 4,350 feet. The Gravehals tunnel which is the longest work of its kind in northern Europe, has its western entrance at about 95½ miles from Bergen, at an elevation of 2,818 feet above sea level. From the Bergen portal the tunnel has a grade of 5 per cent for some distance, followed by a stretch of 3 per cent to its highest point, where there is a dead level stretch 590 feet long, followed by first a 3 per cent, and then a 5 per cent downward grade to the eastern portal the drop continuing until Myrdalen, approximately 109 miles from Bergen, where 2,839 feet altitude is reached.

Owing to the timber line in this district being at 2 460 feet altitude, so that the tunnel portals are fully exposed to wind and weather its construction was an exacting task. Boring was carried out from both ends, the contract price being $808 000 complete. For the supply of electric energy the Kjos Fall was harnessed and the current transmitted to the two ends of the tunnel the aggregate of the water turbines on the west end being 280 horse-power. On this side two Brandt boring machines working at an average pressure of 80 atmospheres were used together with four Frölich and Klüpfel pneumatic boring machines as the former system could not be used for the full section. On the eastern side hand boring was resorted to. The estimated rate of progress was 197 feet per month on the west and 50 feet per month on the east side, respectively. The results of the first year's working however were so far below the estimated progress owing to the extreme hardness of the rock that the contractors had to improve their methods in order to be able to keep to the contracted time for completion. Accordingly on the east side hand boring was first superseded by electric boring machines driven by a small petroleum motor, but being unsatisfactory were discarded in favor of pneumatic appliances with which such advance was made that the two headings met two months before the contract time. The tunnel however was not completed for nearly two years later which delay however exercised no significance inasmuch as the adjoining sections of track were behind owing to the scarcity of labor.

This latter factor proved a difficult problem. The works were far from civilization and owing to the exposed position of the site the privations were so severe that men refused to be attracted to the spot, especially as they could secure plenty of work at the same wages in more congenial centers. The conditions under which the tunnel was driven were certainly unique. Once work had to be suspended for some six weeks owing to an avalance crashing into the power house on the west side, and carrying half of it away. On another occasion a stoppage of two months' duration became imperative, as no water was obtainable, while the extreme severity of the

THE BERGEN-CHRISTIANIA RAILWAY

climate was also another deterrent factor in rapid construction

After issuing from the Gravehals tunnel the line commences another ascent rising 1 411 feet to gain the summit at Taugevandet 14 miles beyond Myrdalen When the line has traversed 1¼ miles east of the Gravehals tunnel the grade being located high on the mountain side another long tunnel the Reinunga is entered This is the second most important work of this class on the line system being 5 217 feet in length and with a continuous grade against east bound traffic of one per cent for the whole of its length This tunnel was bored throughout with electric boring machines the current for which was secured from the power station on the east side of the Gravehals undertaking where 100 horsepower was set aside for this purpose

In June 1898 while work on this section was in progress the government decided that the line should extend eastward from Taugevandet via Gulsvik and Roa where it was to be linked up with the existing eastern railway system After leaving Taugevandet the descent immediately commences and the grade is much easier than that on the western mountain slopes the total drop between Taugevandet and Haugastol 23½ miles farther on being approximately 950 feet The country is then gently undulating for a short distance when there comes another sudden descent to Aal at 169 miles from Bergen at an altitude of about 1 414 feet On the eastern slopes of the mountains owing to the valleys being wider the alignment of the line was appreciably facilitated The descent still continues until at Bromma 205 miles east of Bergen it is at an altitude of about 400 feet

The grade is gently undulating onwards to Gulsvik after which is another slight ascent to overcome the foothill range which is pierced at Haversting at

THE BERGEN-CHRISTIANIA RAILWAY

an altitude of 460 feet by a tunnel 7 644 feet in length which owing to the hardness of the rock proved a difficult undertaking work being carried out first on time then by contract and finally by piece work in order to accelerate progress Issuing from the tunnel the descent is effected with easy grades to mile 262½ when another sharp climb becomes necessary from 300 feet to 1 000 feet through Vassjö and an immediate equally steep descent into Roa where a junction with the eastern railway system leading into Christiania is effected The total length of the line from Bergen to the capital is approximately 306 miles

Altogether there are no less than 184 tunnels on the line representing a total length of about 24 miles The constructional work entailed the excavation of nearly 35 500 000 cubic feet of earth and 28 000 000 cubic feet of rock on the high mountain section while the consumption of dynamite for blasting ran into 1 540 000 pounds There are 57 stations between the two terminal points and owing to the later extension of the line eastward from Voss being of standard gage that between Voss and Bergen had to be altered from the meter gage to secure uniformity In addition to the tunnels there are fourteen large bridges the largest three of which are in masonry one having a span of 150 feet and another being 566 feet in length with eight 70-foot spans Owing to the exposed nature of the line in the upper sections above the timber line extensive fencing as a defense against drifting snow was necessary beside the track these screens being almost continuous for 60 miles between Mjolfjeld and Gjeilo The line passes through a wilder stretch of country than any other European railway The winter lasts nine months, and sometimes longer the snowfall is heavy and the rain storms terrific with a tremendous downpour The line cost about $15,800 000 to build, and the difficulties of construction are only equaled by those experienced in keeping it open for traffic Three American rotary plows are used in winter and one is always kept ready for service as it has to be requisitioned on one or more occasions every month during the year and a heavy snow block in midsummer is by no means a rare occurrence The provision of the line however has reduced the time of transit between Bergen and Christiania from 54 to 14 hours, and is an important highway for traffic Numerous extensions are already projected with a view to bringing the eastern and the western industrial centers into closer communication

Expiration of the Bradley Patents and the Manufacture of Aluminium

The patents covering the fundamental processes for the electrolytic separation of aluminium as originated by C M Hall expired some years back December 8th, 1908 and February 2nd 1909, marked the expiration of C S Bradley's patents for a continuous process. It is thus perhaps an opportune moment to give some attention to the general subject

Chemical and geological investigations disclose the fact that so far as the terrestrial crust is concerned aluminium is the third most abundant substance Yet aluminium is not cheap How then is expensiveness to be reconciled with abundance? About 1885 aluminium was worth approximately $12 per pound The great fact which makes the apparently contradictory one consistent is that aluminium has been exceedingly difficult to isolate from its compounds But in combination with other elements it forms so it has been calculated 7 81 per cent of the materials accessible to us Its price to-day is quite low comparatively to what it has been so that it is coming into large use in industrial applications

Aluminium was first isolated in 1827, but its form was then only that of a powder and this powder could not at that time be melted into a coherent mass In deed it was not quite pure A quarter of a century later (1854) Deville succeeded in obtaining it in a form which could be melted without oxidation In the early part of 1856 aluminium is said to have been worth about $90 per pound but by autumn it had suffered a decline of 70 per cent Three years later the price was about $12 per pound At this point it remained until about 1886 In 1887 it fell to $8 in 1888 to $4 84 The following year when Hall's fundamental patents were issued the price tumbled to $2 During recent years it has been merely a fraction of a dollar Up to about 1856 there had been produced a total of perhaps something over a hundred pounds At present it is manufactured in thousands of tons annually In nature aluminium occurs as a more or less pure oxide in the form of corundum sapphire ruby and emery But the ores from which it is now commercially obtained are chiefly bauxite and cryolite

While still in his twenties Hall sought and found a method by which aluminium could be obtained electrolytically In the successful application of electrolysis use is made not of an aqueous solution of the aluminium but of an anhydrous one He found that a bath consisting of a mixture of a fluoride of aluminium and of a metal more electro-positive than aluminium (as sodium etc) would when at a sufficiently high temperature dissolve the oxide of aluminium (alumina) Two electrodes are now introduced into this heated mass and an electric current of proper electromotive force is started At the positive electrode, oxygen will be given off, at the negative electrode, aluminium is released Now it will readily be understood that, in practically carrying out this procedure, it would be necessary to maintain the heat of the bath Hall's patent (No. 400,766) specifies the use of a suitable furnace. The vessel containing the bath might be of iron or steel This could be lined with carbon. The lining would then, so the inventor states, serve the double purpose of protecting the metal vessel and of acting as one of the electrodes He suggests the use of the mineral cryolite and of the fluoride of aluminium, in proper proportions, as the proper constituents of the solvent. The aluminium melts and collects in globules on the negative electrode—as the carbon lining—and drops down to the bottom of the crucible The specific gravity of the metal is quite low (about 2 6 when solid), but that of the bath is lower still.

In carrying out this process of Hall in a commercial manner perhaps the most noticeable departure has been in connection with the manner of fusing the materials entering into the bath and of maintaining that fused condition Hall prescribed an external application of heat He probably thought of no other possibility But in practice it has been found desirable to supply heat by means of the same current which effects the electrolytic action A heavy current is needed to perform the double duty At Niagara Falls the Hall process was early carried out in the following way Long carbon-lined iron tanks were provided These constituted the cathodes or negative electrodes With in these tanks the materials for the bath were placed Into the bath a row of carbon electrodes depended from a longitudinal support Thus were secured the positive and negative ends of the circuit A number of these tanks were connected in series The aluminium ore used was bauxite, an hydroxide of aluminium employed to furnish the alumina (Al_2O_3) for the bath Bauxite as found in Georgia and Alabama contains in the neighborhood of 65 or 70 per cent of alumina. In the electrolytic action which takes place the aluminium melts and drops down to the bottom of the tank the oxygen set free from the alumina it has been said attacks the carbon of the anodes and forms carbon monoxide The chemical equation for this reaction is

$$Al_2O_3 + 3C = 2Al + 3CO$$

As this gas rises to the surface of the heated bath it burns to carbon dioxide The formation of the carbon monoxide (CO) at the anodes involves the consumption of carbon at that point. So it was found necessary to lower the line of anodes into the bath as time went on

The ore which Bradley seems to have had particularly in mind was cryolite the double fluoride of aluminium and sodium found on the coast of Greenland However the Greenland ore contains only about 13 per cent of aluminium Its use is attended with the disengagement of an impure fluoride gas. With bauxite on the contrary the disengaged or resulting gas is only carbon dioxide which may be discharged into the open without ill effects

One may wonder why it has seemed desirable to get away from the use of external heating It was found that action on the crucible both from within and from without resulted in rapid deterioration.

The modification of the original process of Hall which eliminated the external method of heating the bath seems to have been due to C S. Bradley The broader of his two patents appears to be No 468,148 which was issued February 2nd 1892 Let us consider the process as here disclosed. In a pile of the materials in pulverised form from which the aluminium is to be electrolytically derived a cavity is made at the summit To begin operations two electrodes are first brought into contact, a suitable current having been turned on and an arc formed The electrodes with the arc between them are now pushed down into the heap The materials in the immediate vicinity of the arc are fused Since the fused material forms a fair conductor, the arc now ceases But the fused condition is maintained because of the electrical resistance to the passage of the current The aluminium is set free at the negative electrode, and drops to the bottom of

the fused mass. Fresh material is added as the process goes on. There is here no tank at all, the unfused portion of the material serving the purpose However this material may be confined in a holder protected by the unfused material Again the pile of material may be placed on a carbon slab which together with a small carbon forms the negative electrode To begin operations, the arc is developed between the large and small carbons as before When the action has proceeded far enough to provide a fused mass between the slab and the positive electrode the small carbon may be withdrawn

Scientific Error and Gas Engine Design

Necessary Reversals of Former Engineering Opinion

RAPID as has been the development of the internal combustion engine in comparison with that of other prime movers it is worth considering whether progress might not have been even faster had it not been for certain widespread misconceptions as to its scientific basis The history—short as it is—of the internal combustion engine contains several instances in which for a period of some years the most powerful authorities on the subject were urging the acceptance of incorrect theories and were drawing quite wrong deductions from the practical observations they made As it is proverbially easy to be wise after the event so it is now easy to see the many grave errors and mistakes that were made and to realize in addition how with a slightly fuller consideration of the matter they could have been avoided

The two chief directions in which a reversal in the generally received opinion has been found necessary are those briefly denoted by the terms stratification and gaseous specific heats The former of these unfortunate misconceptions had a great influence on the development of the gas engine The idea underlying it was introduced by the German engineer Otto in the year 1876 when he patented his famous engine His idea was to increase efficiency so that the then very high rate of gas consumption should be reduced to a more economic figure and that the noise and vibration due to the running of such plant which was so undesirable a feature of its operation should be minimized To bring this about he altered the way in which the charges of air and gas were admitted to the cylinder His plan was first to admit air then a poor mixture and finally a rich one Furthermore he was careful to keep in the cylinder a portion of the burnt products of the previous explosion This he claimed had the effect of arranging in layers —or stratifying - the different kinds of gases and gaseous mixtures Next to the cylinder there was to be a layer of burnt products then a layer of pure air then a layer of a weak mixture and finally a layer of mixture of full strength This laminated mixture was to be ignited at its richest point and the flame was to proceed from layer to layer this it was argued would have two benefits—the provision of a cushion or buffer between the explosion and the piston and the lengthening of the time of combustion to a period approaching that of the whole stroke In point of fact these deductions were not correct The charge as it comes into a gas engine cylinder does not stratify and any part of the gaseous substance would act—or fail to act—as a buffer equally well Indeed the way in which combustion proceeded throughout the cylinder was not different—in any material way at any rate—from that customary with the gas engines which preceded the Otto patent Although this was so Otto produced an engine which was a great improvement on any of its predecessors and this undoubtedly influenced those who listened to his arguments Even men like Slaby Dewar and Bramwell supported his case when the fight over the patents had to be faced and largely as a result of their support the Otto patent was enabled to rule the gas engine industry for fourteen years Once it lapsed all manufacturers eagerly adopted it From this misunderstanding of the principles of the operation of the engine there issued the temporary creation of a monopoly and the consequent compulsion on all other manufacturers to use their ingenuities in the manufacture of less efficient models This error in a proper understanding of the principles of operation greatly hindered the development of the engine

Had it been realized in 1876 that the real merit of Otto's engine was its mechanical perfection coupled with the adoption of "compression the patent could scarcely have been upheld since Beau de Rochas in 1862 had filed a patent laying down in the clearest terms the ideal direction in which gas engines should be developed and had placed great emphasis on the necessity for compressing the charge before igniting it Not only this but in the previous year 1861 Gustave Schmidt in a paper read before the Institution of German Engineers had advocated compression It seems in fact that the idea was much in the air and was seizing the imagination of many workers Nevertheless from 1862 to 1876 no engines were made to work on this principle and the great move forward was left to Otto Although Otto adopted this method he attributed its success to more novel reasons than compression the matter thus became the subject of a patent and others were forbidden to enter the field Otto's idea that combustion continued throughout the stroke stood its ground for a very long time despite all that students of the subject of combustion could say to the contrary Indeed it may be said to have some life still though of a not very vigorous kind It is possible that in special cases combustion may be delayed by the existence of pockets in the cylinder or by skin effects but it is doubtful whether such delay occurs at all in normal circumstances This is however one of the points under investigation at the hands of the Gaseous Explosions Committee of the British Association which was appointed at the Leicester meeting to report upon this and other allied matters Mention of the work of the committee brings us naturally to the consideration of the other of the great fallacies which have blocked the path of progress in the gas engine industry and which the committee has done much to clear up The amount of this blocking' is different both in kind and in degree to that due to the stratification fallacy It has not had the effect of creating a temporary monopoly but it has deprived the gas engine designer of the scientific guidance to which he is entitled to look It is as though a traveler in a little known country should find all the sign posts turned through an angle sometimes large and sometimes small but always unknown A wise traveler in such circumstances would probably pay no attention at all to any of them and this is very much what the gas engine builders have done They ceased to believe that the theory of thermodynamics was going to be of any use in the practical work of engine design The temptation to adopt this attitude became the greater as manufacturers realized earlier than the scientists that there was something wrong with gas engine thermodynamics The common scientific theory taught that gas engines were ideally capable of a much greater increase in thermal efficiency than the manufacturers knew to be possible The reason for this discrepancy was that the scientists worked out efficiencies on the basis of constant specific heats whereas the manufacturers worked with a real substance and not with a dream stuff Theorists taught that the amount of heat contained in the gaseous products in a gas engine was exactly proportional to its temperature whereas in point of fact the amount of heat reckoned from 100 deg C instead of exactly doubling between temperatures of 1 000 deg and 1 900 deg C was really nearer the ratio of 2½ to 1 The difference between 2 and 2½ in these calculations as in most others is very great and renders the old theory inapplicable The suggestion from the scientific side that there was something wrong with the basis of the old theory came from France where two eminent physicists MM Mallard and Le Chatelier measured the specific heat of different gases at various temperatures and found a very marked difference in the values for high and for low temperatures

This idea was not at first received with much cordiality in England and even now the accuracy of the French figures is doubted Still there has been a great shift in the point of view and the Gaseous Explosions Committee which contains representatives of all schools has admitted the reality of the French physicists suggestion as beyond doubt although declining to commit itself to actual figures pending the result of certain experiments now being undertaken notably by Mr Dugald Clerk and by Prof Hopkinson The committee has however given in one of its reports a curve of specific heat which is considered to be accurate within 5 per cent It is not difficult to show by the use of such a curve that a gas engine which was previously thought to be capable ideally of 54 per cent efficiency is really only capable of about 43 per cent when the real nature of the actual working medium is taken into account as naturally it should be This is only one instance but the principle applies to all engines It cannot therefore be thought surprising that gas engine manufacturers should have looked somewhat askance on gas engine thermodynamics Had this grave misconception as to the nature of specific heats not arisen there can be little doubt that the designer would have been able to benefit materially by scientific guidance in a way which the circumstances described made impossible In spite of all difficulties however gas engines are now built for the market which achieve thermal efficiency as high as 80 per cent of the theoretically attainable limit for the cycle upon which they work And it will be interesting to learn later on the corresponding percentage of Mr Humphrey's ingenious gas pump which works on a different cycle to that of most gas engines and should have a higher range of efficiencies within its horizon

As an instance not of the effect of prevalence of error but of a condition of entire ignorance we may refer to the recent work of the Gaseous Explosions Committee in the direction of radiation No one had suspected previously that gaseous radiation played the important part it does in gas engines particularly in those which operate at high temperatures Indeed it has yet to be definitely settled whether the glowing gas is very transparent as Prof Hopkinson says or merely fairly transparent as Prof Callendar says to its own radiation In the former case the phenomenon is volumetric and in the latter it would be partly a surface and partly a volume effect It is now beyond doubt however that the amount of this radiation rises with extreme rapidity once the temperature exceeds a certain amount and this accounts for an important fraction of the considerable heat loss at such temperatures so providing a hitherto unsuspected reason for keeping the temperatures as low as practicable With a rich charge and a high compression it is not easy however to keep the temperature low unless on the cycle followed by the Diesel engine where the fuel is admitted by easy stages instead of all at once

To recapitulate the error of stratification was the means whereby a partial monopoly to manufacture was secured and it prevented the best men not already working for the Otto people from developing their own engines on the lines along which useful progress alone was possible The error in gaseous specific heats which still remains in many books on the subject has put the manufacturer out of sympathy with scientific work as he felt he knew better The existence of this error is now realized but it must be a few years before the new experimental work of the physicists has been sufficiently scrutinized and verified to enable science to venture to give a responsible lead to those who as manufacturers have for so long had to depend on themselves —*The Engineer*

The Mixing of Concrete

THE question as to how much water should be used in mixing concrete has often come up for discussion among engineers in Europe and opinions seem to be divided in this regard The German Concrete Association has been giving this matter its attention for some time past, apropos of the standardizing of concrete testing methods In order to elucidate this point, tests were made by preparing concrete in two different places and by different workmen A great number of samples were then prepared having an aggregate weight of nearly 100 tons. During a period of five years these men put through a series of tests as to resistance to various strains These experiments are now completed and the results have been published Among other results the work carried out at the testing laboratory of the Stuttgart Technical School with samples made at the laboratory itself by the same workmen and under the same conditions showed that for a proper composition of concrete the maximum strength appears to be obtained by using the smallest possible amount of water compatible with the production of a good mixed concrete

However the use of the minimum amount of water requires the great st are and can only be practised by very skillful workmen Otherwise it is to be feared that the concrete will not be homogeneous The conclusion is drawn that in proportion as the workmen are less skilled greater security is given by increasing the amount of water It is also to be noted that other factors enter in here such as the variable humidity of the sand gravel etc variations in the hygrometric state and temperature and others and that these also have an influence on the amount of water needed

Relics of the Spanish Armada

How a Treasure Ship was Located at Tobermory Bay

After keeping them securely hidden from human eyes for three hundred and twenty-two years the waters of Tobermory Bay off the coast of the island of Mull, England, have at last given up some of their treasures in the form of a motley collection of battered and worn relics of no value except to historians and antiquarians, but to them of priceless worth, as they tell the story of the tragic end of the famous Spanish Armada better and more graphically than could pages of histories.

Capt. Burns, the principal wreck officer of the Glasgow Salvage Association, who was in charge of the operations, was untiring in his efforts in bringing these woful remnants of the once splendid Invincible Armada to light again. They were recently placed on exhibition at the Glasgow East End Industrial Exhibition, where they attracted the greatest attention.

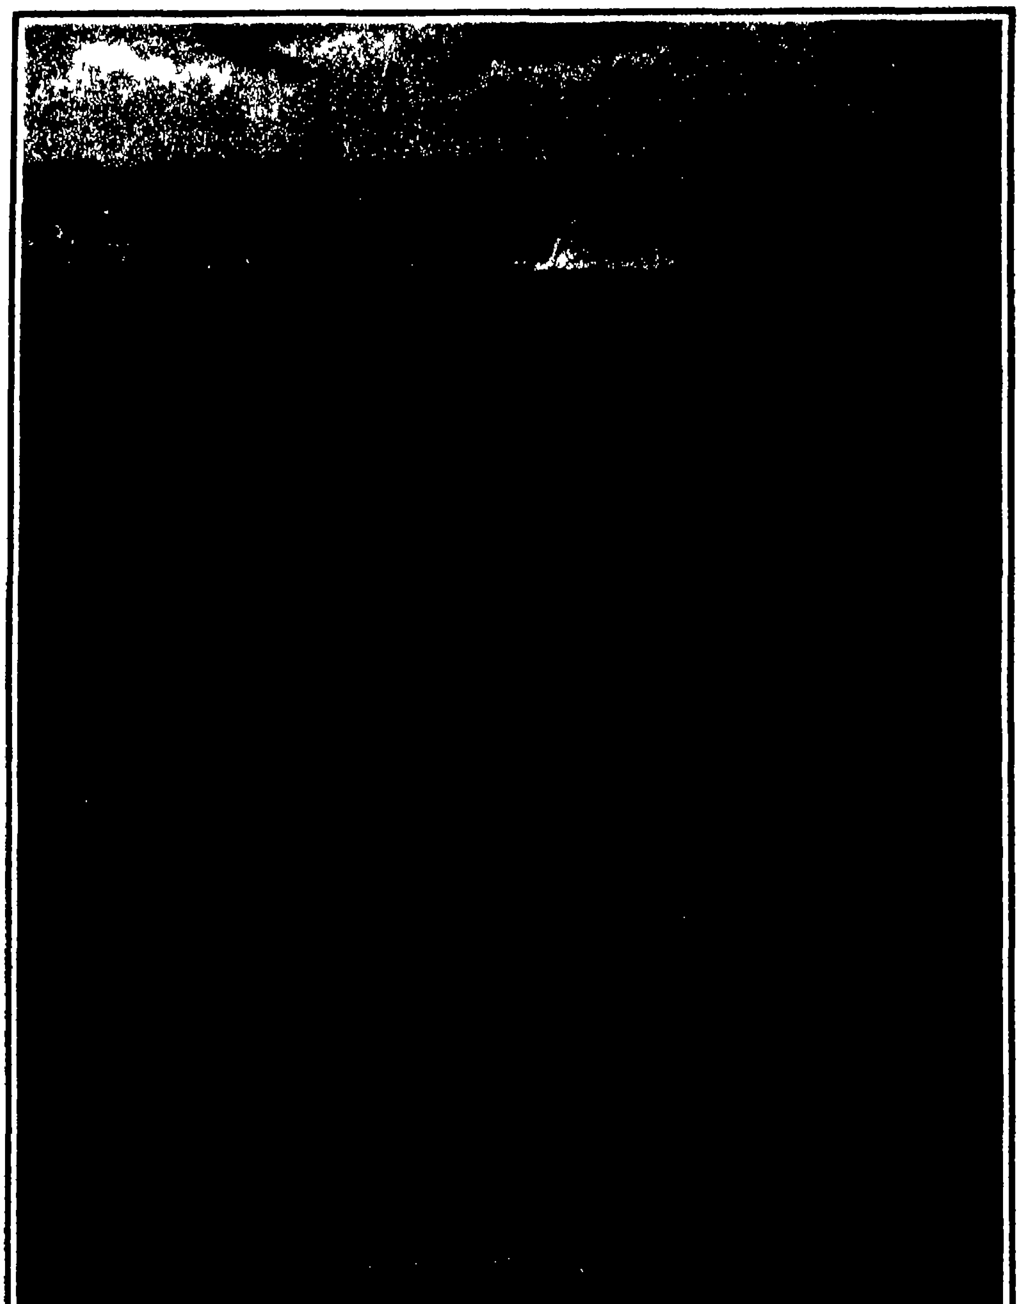
As tangible trophies of deep romantic interest these exhibits clearly prove that tradition did not lie when it said that on the spot where the relics were found by Capt. Burns there was blown up in August, 1588, one of the richest of the ill-fated ships.

It was with the permission of the Duke of Argyll that Capt. Burns pursued his investigations, for since the wreck of this particular vessel was given into the possession of a Marquis of Argyll by royal grant scarcely half a century after the Spanish squadron met its fate off the coast of England and Scotland, the title of that noble family to the ownership of whatever the waters of Tobermory Bay held of the vessel of the Don has been undisputed.

The tradition of this particular bit of the stormy history of England has scarcely changed in a single point in spite of having been handed down from father to son for three centuries, and the recent discovery of the relics has only added to its authenticity. The name of the vessel which was blown up has been spoken of as the "Florida" in old records, but it was really the "Florencia," a Florentine galleon which came from the Levant, one of the Italian possessions of the King of Spain, and was commanded by one Pereija.

By far the fullest account in Scottish history of the loss of this ill-fated ship is to be found in the records of Clan MacLean, whom it most closely concerned. In the year 1588 the chief of the House of Duard was Sir Lauchlane MacLean, who had at that period seriously embroiled himself with his neighbors the Clanranald and the Clan Ian in numerous bloody feuds, and as a result of these had been "denounced rebel" by King James.

Soon after this the "Florencia," commanded by Capt. Don Pereija, was forced by stress of weather and want of provisions into Tobermory Bay. The captain sent peremptory orders to Sir Lauchlane MacLean to supply his ship with such provisions as he might require or as the island could afford. No reply having been made, he threatened to use the means within his power to enforce his request. The haughty chief of MacLean replied to the effect that "the wants of the distressed stranger should be attended to after he had been taught a lesson of more courteous behavior, and in order that he might have such a lesson as speedily as his wants seemed pressing, he was invited to land and supply his wants by the forcible means threatened, for it was not the custom with the chief of MacLean to pay ready attention to the wants of a threatening beggar."



By courtesy of the London Graphic.

THE SEARCH FOR SUNKEN TREASURE AT TOBERMORY: HOW THE SPANISH ARMADA SHIP WAS LOCATED AT BOTTOM OF THE BAY

The search for the Spanish Armada ship which sank in Tobermory Bay, Isle of Mull, in the autumn of 1588. The vessel which has now been found is believed to be the "Florencia," one of the Italian contingent in the Spanish Armada, which is said to have carried thirty million pieces of eight on board. A number of these coins have already been recovered, together with large quantities of black African ... sword hilts, scabbards, muskets and stilettos. The "Pieces-of-Eight" Syndicate, which is now conducting the search for the sunken treasure, has carried on operations since August, 1910, with divers, a borer similar to that ... and a powerful suction plant, all of which may be seen at work in the engraving.

The Spanish commander very discreetly decided to decline the invitation and now promised payment for whatever necessaries in the way of food and clothing might be supplied him. Finally a sort of friendship sprang up between the Don and his Highland host, and in return for the provisions supplied him he offered Sir Lauchlane the assistance of a hundred of his marines, and with this help the Scot proceeded to make war on his neighbors. He first ravaged the islands of Rum and Eig, then held by the Clanranald, and the islands of Canna and Muck, the property of the Clan Ian. After devastating these he made a descent upon the mainland of Ardnamurchan, and, still with his Spanish contingent, laid siege to MacIan's castle of Mingarry.

In a word, he swept through the neighborhood with fire and sword, working havoc wherever he went.

While he was engaged in this way he received a message from Capt. Pereija requesting that the Spanish soldiers be sent back at once, as he was preparing for sea. At the same time he heard that the provisions supplied to the Spaniard had not been paid for. Sir Lauchlane remonstrated with the Don for his injustice, and full satisfaction was promised. On the strength of this the men were sent back, but MacLean, not relying entirely on the captain's promise, retained three of the soldiers as hostages till the debt should be paid. At the same time he sent one of his own men, Donald Glas MacLean, on board the "Florencia" to receive an adjustment of the demands of his people. The emissary was at once disarmed and made prisoner, and no communication was allowed between himself and his friends. But Donald Glas conceived a plan, which, though it meant certain death to himself, promised a speedy and terrible retribution to his captors.

Finding that the cabin in which he was confined was close to the magazine, he found an opportunity to force his way into it, and laying a train from it to the outside he fired it, and the ship was blown to pieces, killing the three or four hundred on board.

The wreck of this vessel and the enormous treasure which she was reported to contain created a great deal of interest in the spot where she had sunk. They early excited the interest of the Argyll family, and in 1611 the Marquis of Argyll obtained as a gift from Charles I the vessel, provided he paid to the Duke of Lennox and Richmond the one hundredth part of the ship after the deduction of expenses. In 1665 the Earl of Argyll entered into a contract with one James Mauld, wherein the latter agrees to give the former one-fifth part of all that shall be recovered from the ship of the Armada lost beside Tobermory. These contracts have gone on and on, but no great store of gold and silver has been found, nothing more in coin than a few pieces now and then, though some fine brass cannon have been found.

Among the articles recovered, apart from old timber, warped ironwork, stone and iron cannon balls, human bones and skulls and silver coins, there is also a bronze breech-loading gun 4½ feet in length, one of the fifty-six carried by the "Florencia."

The gun is still in such a condition that although it lay in twelve fathoms of water for more than three centuries the monogram of the maker, supposed to have been Benvenuto Cellini, and the date, 1563, are still visible. The ball with which the gun was loaded still remained in it. The breech action is lifted out of the gun by a handle similar to a laundry smoothing iron.

A projection fits into the bore, and the wedge-shaped hole at the side of the gun has apparently been used to fasten the breech block and prevent it from being forced back by the firing of the charge. When the breech-block was removed it was found not to be solid but to have been used as the powder chamber. The iron bullet was found in direct contact with the powder, and in front of it were the remains of a wad of rough fiber, apparently manila oakum. The bore of the gun is one and five-eighths inches. A round hole at the end was for use in ramming and cleaning out the gun between the shots. This gun, therefore, takes its place among the earliest known

... gum. The [illegible] of which it has been made was not affected by the water

The broken blade of a sword, a pistol, and a hook and tackle, thickly incrusted with limestone, have also been found as well as a piece of the woodwork of the ship in a fossilized condition

The tradition is that the Florencia had fifty six guns on board and thirty million pieces-of-eight The latter still repose beneath the sand and mud of the bay making their recovery very difficult even by the methods at present in operation which are shown in the illustration

The Destruction of Weeds by Chemical Means—II*

An Important Agricultural Problem

By Harold C Long, B Sc, Author of "Common Weeds of the Farm and Garden

Concluded from Supplement No 1831, page 77

In the course of his investigations Bolley observed (1) That succulent plants and those of slow growth are more easily killed than others, (2) that flower parts and parts of plants covered with bloom or waxy coatings are more or less protected (3) that plants possessed of hairy surfaces are as a rule, more easily killed than those with a smooth surface (4) that chemicals act differently upon plants of different families even though the plants be wetted equally readily—charlock and dandelions for example, are readily attacked by copper sulphate solution while creeping thistle, wild buckwheat and clover are slowly attacked, and (5) that most of the chemicals readily destroy the tissues of any plant where the surface is broken

It was found that charlock could be sprayed with absolute success that king head or greater rag weed (*Ambrosia trifida*) could be sprayed in much the same way as charlock and with considerable success at certain times success depending on the age of the weed that creeping thistle (*Cnicus arvensis*) was most effectively sprayed with sodium arsenite (one and a half to two pounds per fifty two gallons of water) and common salt (one-half barrel per fifty two gallons of water) that succulent portions of the stem and leaves were destroyed when the plants were

Fig 10—Garden Nightshade (*Solanum nigrum* L) A Pest of Arable Land and Gardens and Poisonous to an Extent Which Varies According to Conditions

a foot high and seeding was prevented that spraying of dandelions on lawns and fields with sulphate of iron was a marked success and that the perennial sow thistle (*Sonchus arvensis*) was practically unaffected by sprays (It may be remarked that this weed only too common in Britain is quite smooth and covered with bloom)

Bolley concluded that the following weeds may be eradicated or largely subdued in grain fields by the use of chemical sprays False flax (*Camelina sativa*) worm-seed mustard tumbling mustard common wild mustard (charlock) shepherd s purse pepper grass ball mustard, corn cockle chickweed dandelion creeping thistle bindweed plantain rough pigweed, king head Red River weed rag weed cocklebur The following were found not to be effectively controlled by chemical sprays as now used Hare s ear mustard penny cress, pink cockle perennial sow thistle, lamb s quarters pigeon grass wild oats chess (*Bromus secalinus*) couch grass sweet grass and wild barley

A large number of tests with the sulphates of iron and copper were carried out some years ago by Dr A. B Frank in Germany[1] Thirty five species of weeds were involved Clover was but little damaged by a 15 per cent solution of iron sulphate (seventy gallons per acre, and one hundred and sixty gallons per acre), or a 5 per cent solution of copper sulphate the clover soon recovering after losing its first leaves In addition to charlock the following plants were more or less damaged by sulphate of iron Corn cockle poppy sow thistle corn flower

Fig 11—Corn Buttercup (*Ranunculus arvensis* L) × 1 Often Very Troublesome in Corn Fields on all Soils Especially on Chalk Often Termed Watch Wheels From the Flat Spiny Fruits

field thistle dandelion groundsel and the following were more or less damaged by a 5 per cent solution of copper sulphate (seventy gallons per acre) spurrey groundsel black bindweed Though these plants appear to be rarely destroyed they are prevented from producing flowers and seed

In experiments conducted in 1903 at the Holmes Chapel College of Agriculture and Horticulture clover was untouched when the covering oat crop was sprayed with one hundred gallons of a 4 per cent copper sulphate solution In 1899 a 4 per cent solution of the sulphate (one acre) completely killed *Polygonum Persicaria* but clover was uninjured A 4 per cent solution of copper sulphate (fifty gallons per acre) was also used to destroy charlock in mangolds the latter being uninjured

Experiments at the Agricultural Experiment Station of the University of Wisconsin showed[2] that a

Fig 12—Shepherd s Needle Venus s Comb (*Scandix Pecten Veneris* L) × 1 An Annual Corn field Weed Sometimes Extremely Troublesome on Light and Chalk Soils

20 per cent solution of iron sulphate (fifty two gallons per acre) did not injure cereals clover seedlings or lucerne, but cockle-bur ragweed dandelions daisies, wild lettuce and several common farm weeds were partly eradicated Sow thistles and creeping thistle were not effectively sprayed and it was concluded that their eradication by spraying is not practical for the average farmer

In demonstrations conducted throughout Ontario the effect of copper sulphate was observed in relation to twenty-eight weeds[3] and while charlock was the only species readily destroyed it was found that the flowers of field bindweed and white cockle and the leaves of creeping thistle sow thistle blue weed (*Echium vulgare*) and bull thistle (*Cnicus lanceolatus*) were very sensitive to the spray and largely destroyed

At the Yorkshire College Leeds experiments showed[4] that clovers were practically uninjured when sprayed with a 12 per cent solution of sulphate of iron while peas beans carrots onions beet, and parsnips were but slightly damaged and this was

Fig 13—A Plot of Lawn Upon the North Dakota Agricultural College Campus Infested by Dandelions Untreated Before Blossoming Time Left Continuation of Fig 14

Fig 14—A Plot of Lawn Upon the North Dakota Agricultural College Campus Infested by Dandelions of the Same Strength of Growth as Those Shown in Fig 13 but Treated With Iron Sulphate Solution Thrown by a Traction Sprayer Two Weeks Before Blossoming Time Compare With Fig 13 These Two Photographs Show in a Striking Manner the Effects of Spraying

the case also with swedes turnips and mangolds

Spurrey (*Spergula arvensis*) has been found to be checked by spraying with a 3 per cent solution of sulphate of copper (forty gallons per acre) flowering and seeding being checked[5] In another trial[6] the results were held to show that a 3 per cent solution of copper sulphate (fifty gallons per acre) may be relied on to kill spurrey

At the Woburn Experimental Farm it has been shown by pot trials that the common poppy (*Papaver Rhoeas*) is much injured by a 2 per cent solution of copper sulphate when the solution was applied to both surfaces of the leaves these turned brown became shriveled and to a great extent the plant was killed for the seeding was almost entirely prevented the flower heads withering completely It has also

* Knowledge.

[1] Bekämpfung d. Landw Unkräuter durch Metallsalze.—Arb. aus der Biol. Abth. für Land. und Forstw., I. Bd., 1900

[2] Bulletin No 179, 1909

[3] Ann Report, Dept Agric Ontario 1904 Vol I ( )

[4] Report on the Spraying of Charlock and Runch 1899

[5] Rept on Expts. Midland Agric and Dairy Inst 1900

[6] Univ Coll. of North Wales, Bangor Bull 11 1908

been stated that the common scarlet poppy is very sensitive to a 15 to 20 per cent solution of iron sulphate. At the Woburn Station also experiment showed that the wild onion (*Allium vineale*) may be destroyed or at least largely reduced by spraying with a per cent solution of pure carbolic acid.

Dr. Hiltner found that dodder on clover may be destroyed by spraying with a 15 per cent solution of sulphate of iron so applied that it hits both the plants and the surface soil with some force. The clover was blackened at first and appeared to be ruined but sprouted strongly afterwards.

Sulphate of iron has been found to destroy charlock if applied in the powdered condition when the dew is on the leaf, three to four hundredweights per acre being necessary. This is considered by M. Hitier to be more easy of application than in the form of a solution and more practical on small areas.

Calcium cyanamide has also been found useful for destroying charlock in corn crops.

The action of gasoline on certain plants has been observed at the Woburn Experimental Fruit Farm, and it was noted that the poppy, teasel and wild strawberry were practically killed.

The efficacy of carbon bisulphide in killing large tropical weeds has lately been discussed by E. V. Wilcox in a press bulletin issued from the Hawaii Agricultural Experiment Station, and plants appear to be destroyed owing to the freezing effect.

The results of experiments at the Vermont Agricultural Experiment Station and elsewhere are summarized in Farmers' Bulletin No. 124 of the United States Department of Agriculture, and arsenic, sulphuric acid, liver of sulphur, kerosene, copper sulphate, arsenate of soda, and so on, are dealt with.

The foregoing notes show conclusively that in one way or another many weeds may be attacked by means of solutions of chemical preparations, with good prospects of preventing seeding or of destroying the plants altogether. It is, however, still desirable that exhaustive experiments should be conducted on a co-operative basis in different parts of Great Britain for the effects of the various solutions vary with the plant sprayed, the local meteorological conditions and the thoroughness with which the work is carried out. With the results of such experiments placed clearly before them farmers would have some definite information on which to proceed.

Correspondence

Screw Propeller Design

To the Editor of SCIENTIFIC AMERICAN SUPPLEMENT:

Starting with the indisputable fact that any length, width and shape of a propeller blade provided it be given a positive angle will develop more or less thrust, one is forced to the conclusion that the theoretical true-screw principle of construction is not a necessary factor in producing propulsion. Further, it being a matter of record that a propeller with straight pitch, that is, with blade angles not varying from hub to tip, thus defying most theories of propeller construction, developed more effective thrust than a scientifically designed and perfectly constructed screw pitch propeller in actual competition (Lougheed, Vehicles of the Air, p. 241), I am convinced that progress requires the rejection of the screw propeller theory, which after centuries of application (dating from Leonardo da Vinci, 1452-1519) still remains even in the minds of experts (?) a mystery. So that to-day the manufacture of screw propellers continues to be a mere experiment or tentative effort toward maximum efficiency, an effort which is just as likely to be equaled offhand by any schoolboy with the medium of two shingles tacked to the ends of a broomstick.

I advance the idea and claim that every screw propeller—so called—works or advances by the effect of its rotation through the air, not as a result of its pitch angle or angles causing helical travel, but as a result of reaction of the air pressure against the compression side of the blades causing straight ahead travel, and that its rate of advance in feet per second is nothing more nor less than the terminal velocity of a surface equal to the entire area of the propeller's circle of revolution impelled by said reaction pressure against the air pressure resulting from and retarding the progressional velocity of said surface. In other words a propeller is a parachute falling horizontally. The reaction or thrust in the one case taking the place of the aeronaut's weight in the last. (This is an extreme example cited merely to illustrate the idea. In the following paragraphs I will show that efficiency in a propeller will result in great part from the proper relation of its blade widths to rotational velocity, whereby the face it presents will be the least possible percentage of the total area of its circle of revolution.)

This view is supported by the following experiment: Fix a thin blade, say one inch wide and one foot long, with its plane exactly midway and at right angles to the end of a rod. On thrusting this through a body of water or immersing it in a stream running in the direction of the axis of the rod, the resistance will be simply that caused by the water against the mere superficies of the blade. Next put the rod and blade in rapid rotation. The retarding effect against direct motion will now be increased near tenfold and is equal to that due to the entire area of the circle of revolution. By trying the effect of blades of various widths it will be found that for the purpose of effecting maximum resistance the more rapidly the rod revolves the narrower may be the blades. There is a specific ratio between the width of the blade and its velocity. This experiment, though referring to the action of surfaces in water, is yet exactly analogous to the conditions obtaining in air. (Wenham, Aeronautical Annual, 185, p. 90.)

Further support of this idea is afforded by the fact commonly experienced that a propeller which in a ground test gives from 100 to 300 pounds thrust when applied to an aeroplane and given an air test will render as little as 25 per cent and from this figure up to perhaps 30 per cent its ground efficiency. The aviator wonders why and customary thought answers "slip." Again: An advantage of the propeller in affording the starting impulse—of an aeroplane—is that its thrust is highest when the vehicle speed is lowest. Now really why? According to my reasoning because the thrust as measured in the ground test is the actual thrust (or reaction) value acting against the posterior face of the propeller disk, and when the air test is made (and the thrust apparently drops through the effect of slip) what really happens is that the thrust maintains its intensity but the propeller's actual progressional velocity is less than what screw theory demands because at said velocity the air pressure acting against the anterior face of the propeller disk equals and balances said thrust. Again quoting the parachute simile the propeller has reached its terminal velocity.

Now this reasoning explains why a straight pitch fan blower is of little value as a propeller, because its blade tips are so wide usually as to lose efficiency as regards reaction pressures through the phenomena of interference. And this width of blade multiplied by the number of revolutions per second results in the formation of a solid disk opposed to progression.

Conversely the narrow tips and blade widths of Curtiss's straight pitch propeller which defied most theories of propeller construction but proved more efficient than a scientifically designed Chauviere propeller gained that efficiency because its long narrow blades were of the best shape to obtain reaction pressures from the air and their width multiplied by the number of revolutions per second resulted in a total area less—by perhaps 50 per cent—than the total area of their circle of revolution, thus reaching their terminal velocity at a comparatively high speed in terms of miles per hour.

This reasoning also explains the cause of the greater comparative efficiency of propellers of great diameter turning slowly. The peripheral speed of the blade tips obtains great reaction pressures and the low number of revolutions per second do not nearly close the area of the propeller disk, thus letting the air from in front pass between the blades.

A very recent patent has been granted an English inventor for a propeller having perforated blades, for which great efficiency is claimed.

Need I cite more instances? No. Apply my reasoning to any type of existing propeller, true-screw, straight pitch or mongrel. What has been mystery in regard to their action becomes plain by means of the simplest arithmetical calculations. Conversely, following this idea a propeller can be designed for any duty required with much greater certainty of success than by the hit-or-miss system now in vogue.

Los Angeles, Cal. JOSEPH A. BLONDIN

Effects of Forests on Climate

To the Editor of SCIENTIFIC AMERICAN SUPPLEMENT:

I was very much interested in an article appearing in the SCIENTIFIC AMERICAN for October 29th, 1910, subject "Forests in Relation to Climate and Floods." The most of us readers will agree with Mr. Moore when he states that deforestation has no perceptible effect on precipitation. His figures and arguments are as to that fact conclusive. However, we take exception to his deductions with regard to the run-off of water from denuded tracts.

We choose to regard only those facts which have to do with conditions in this country. Our reason is that deductions, not figures, were given for statements with regard to floods in Europe. As far as these facts are concerned we could glean the great fact that floods are not on the increase in Europe, the continent which has perfected the system of forest conservation.

Turning to the facts with regard to our own country two stand out prominently: 1. Ground cultivated to a depth of eight inches is a better conserver of rain fall than the primeval forest humus. 2. In the Cumberland, Tennessee and Ohio rivers the number of flood days has decreased from 2,100 in 1871-1889 to 1,400 in 1890-1908. Either Mr. Moore's general deductions are based on other figures or the deductions based on the above figures are obscure to us.

1. No figures are given as to the percentage of denuded forest land that is put under cultivation. To an observer of the tracts cut off by our western lumber companies it would seem that very little is ever touched by the plow. Usually timber is on the slopes of hills that cannot be and seldom are cultivated. Where cultivation does occur I have yet to see the ground that is ever tilled to a depth of eight inches. This county, in the midst of reserves, is as large as New Jersey, but seldom do the ranchers plow deeper than six inches, the majority are satisfied with scratching the surface. So it is all over our western mountains. We would all admit Mr. Moore's first point if he could show that the greater part of denuded land is cultivated, and this to a depth of even six inches.

2. As to the second point. The mean annual stage of the Ohio varies as the rainfall—that is evident. The relative number of flood days is striking: 2,100 in the earlier period, 1,400 in the later period of equal length. Now it appears at once that in late years, 1,400 flood days have sufficed to carry off an amount of water formerly carried off during 2,100 flood days, the mean stages of the two periods indicating that approximately the same amount of water was carried in each period. It would seem that the floods were more intensified in later years while they lasted, but that they were not of such long duration. Ohio newspapers seem to bear out this fact annually when the freshets occur. Evidently the run-off in the upper reaches of the Ohio has been occurring more rapidly in late years.

We believe that this question is vital enough to ask for a more extended report from Mr. Moore. A diagram showing high and low stages with their durations would get at the crux of the matter. Again are the people of the headwaters of the Ohio ceasing to cultivate their farms? We do not reflect on Mr. Moore's deductions; we believe that he has figures that will more definitely substantiate his conclusions. May we have them? We are open to conviction.

Yampa, Colo. FRITZ TARUSCH

White Cement

COLORED surfaces or objects in cement are made by adding pigment to the surface layer, but the natural color of the cement must be taken into account in selecting and apportioning the coloring matter. For this reason numerous attempts have been made to produce a white cement. Often colored cements are made by adding suitable metallic oxides before the furnace process. Ordinary Portland cement takes its hue from the color of the substances entering into the raw material, such as iron and manganese compounds. Nearly all the clays and marls contain such oxides, so that it is difficult to have a white cement. Dr. Wormser overcomes the difficulty by a process in which he obtained white cement from ordinary clays and even ferruginous clays. The crude mass is mixed with 2 to 5 per cent of sal ammoniac and during the furnacing process this is volatilized and escapes in the shape of fumes. It may be recovered by passing the fumes through scrubbers in which the sal ammoniac (ammonium chloride) is absorbed by the water. Chloride of iron also passes in the fumes. The furnaces should be of the small vertical type and this increases the cost of production, but on the other hand the product brings a higher price. If an absolutely white cement is not needed a more economical process is to use chloride of zinc for treating. The resulting product always retains a small amount of this salt and it has a slight greenish tint.

Coloring Soft Solderings.—To impart to a copper soldering, the copper color, first prepare a saturated solution of pure blue vitriol, this is applied to the soldered place. On passing over the soldering with an iron or steel wire, it will be coated with a covering of copper, which can be thickened as desired by repeated application of the blue vitriol solution and touching with the wire. To impart a yellow color to the soldered spot, prepare a mixture of 1 part of saturated white (zinc) vitriol solution and 2 parts of blue vitriol solution; apply this to the soldered spot and rub with a zinc rod. If we desire to gild the spot, the place coppered is coated with gum or fish sound solution and dusted with bronze powder. As soon as the gum is dry, we can, as in other cases, obtain a bright surface, by burnishing.

A printed copy of the specification and drawing of any patent in the foregoing list, or any patent in print issued since October 4th, 1859, will be furnished from this office for 10 cents, provided the name and number of the patent desired and the date be given. Address Munn & Co., Inc., 361 Broadway, New York.

Canadian patents may now be obtained by the inventors for any of the inventions named in the foregoing list. For terms and further particulars address Munn & Co., Inc., 361 Broadway, New York.

Snow Blindness

IN May, 1883 the explorer Jochelson, traveling alone by sledge in Northern Siberia was overtaken by a snow storm that proved to be literally blind ing." He slept during part of his enforced halt of twenty-four hours and on awakening he found him self totally blind, in an uninhabited region which he was traversing for the first time There was only one hope. He knew that the sledge was headed south ward. He drove his team of nine dogs in the opposite direction as nearly as he could judge and after a long journey in subjective darkness though the sun was shining on the fresh snow he reached the place where he had parted company with his Tunguss guides a few days previously The dogs recognized the spot and stopped But the place was deserted so it was necessary to go on—how far the blind man knew not Again the dogs stopped and pawed the ground and a sound of distant yelping indicated the presence of foxes in a burrow directly beneath the sledge While the blind explorer was trying to straighten the reins which the excited dogs had tangled the team es caped and ran away with the sledge carrying the pro visions and water Jochelson blind and destitute wandered about in the snow for several days until he reached a pile of stones which he conjectured had been employed to anchor a native tent

Under the stones he found a pool of water with which he slaked his thirst but he was so weak that he lay down to die He was rescued five days later

Hygieia the organ of the Dresden Hygienic Exhibition which recalls this interesting story adds that the natives of the Arctic regions have learned how to protect themselves from snow blindness by means which will be exhibited at Dresden next summer The natives of Alaska use richly ornamented wooden eye-shades Some other Eskimo tribes used to wear woolen spectacles pr vi d iti narrow slits but nowadays the aje t res are usually larger and are covered with bits of colored glass obtained from European visitors Ar tic expl rers and Alpine tourists usually protect their eyes with dark glasses

Rats and Plague

By G F Petrie

Altho[illegible] the r nt epidemics of bubonic plague in Chi[illegible] I [illegible] a d ther parts of the world have been always ass iat l with outbreaks of the same disease am ng rats the historical study of p ag e thr ugh o it the world reveals the singular fact that previous to 1800 ve y few references to a r it cident mortality among rats have been put on record Many ex cellent a c unts f tl ld r outb eaks notably of the Bla k Dea l in E u ope in 1347 and the Great Plague of L ndo 1 1665 are in existence but careful re sear h into these d xun ents by mo lern historiog raphers—Haeser Hirsch Abel and Sticker—has shown that for reasons difficult to dis over very scanty mention of associated rat mortality has been made

The earliest recorded instance is perhaps that given in the Bible in the acc unt of the pestilence among the Phi istines which they ascribed apparently to the mi e that marred the land Avicenna refers to the association between rats and plague in his de scription of the epidemic in Mesopotamia about the year 1000 A D Nicephorus Gregoras writing of the Great Plague of 1348 which entered Europe by way of Constantinople makes a similar reference Rats are mentioned in connection with the plague in Yun nan about 1757 and later in 1871 3 In India an as sociation between rats and plague is noted in the *Bhagavata Purana* by the Emperor Jehangir in the plague epidemic of 1615 and in a report of the Pali plague in Rajputana in 1836 Lastly Orreus refers definitely to rat mortality in his account of the epi demic of 1771 in Moscow

The identity of the disease in rats with that affect ing man was established by the discovery in 1894 of *B pestis* by Yersin and Kitasato

Within the next few years the relationship b tween rat and human plague was investigated i many parts of the world—by Thompson and Tidswell in Sydney Clark and Hunter in Hongkong Snow Weir Hankin and James in India and by Kitasato in Japan In 1905 the Plague Research Commission was appointed to investigate plague in India and the reports of this commission represent the results of the most exhaus tive inquiry into the subject that has yet been carried out

The commission early turned its attention to the relationship of rat plague and human plague and instituted an extensive examination of the rats in Bombay and elsewhere for the presence of plague in fection The maps and charts representing graphic ally the results of this examination clearly show the correlation between the epizootic and the epidemic—the rat epizootic preceding the epidemic by an interval of ten to fourteen days Every outbreak of bubonic plague when adequately investigated was found to be associated with the disease among rats The conclusion must be drawn that every epidemic of bubonic plag ie is caused by the concomitant rat plague

In Bombay the rat population is an enormous one *Mus decumanus* (the brown or gray rat) swarming in the sewers gullies and outhouses in the city and *Mus rattus* (the black rat) living in countless numbers in the houses of the people The latter species is of especial importance in plague epidemics because it is essentially a house rat it may almost be said to be a domesticated animal The severity of the epizootics in the two species will be appreciated when it is stated that during one year the examination of 70 789 *M decumanus* taken from all parts of Bombay city proved that 13 277 were plague infected = 18 8 per cent, and that out of 46,302 *M rattus* [illegible] were plague-infected = 9 4 per cent The higher in cidence of plague in *M decumanus* is explicable by the circumstance that the flea infestation of this species is more than twice that of *M. rattus*

Some interesting observations on the distribution of different species of rats in India have been made re cently by Capt R. E Lloyd I M.S The most com mon rats in India are *M rattus M decumanus* and *Gunomys* (*Nesokia bengalensis*) *M decumanus* is common both in Bombay and Calcutta, but is absent from the city of Madras It is significant that Madras is the one port in India which has never been seriously infected with plague *M rattus* appears to be uni versally distributed in India, whereas *M decumanus* does not seem to occur in India except in seaports *Nesokia bengalensis* is found in every part of India

The question of the transportaion of plague by ship rats is an extremely important one but has not so far been thoroughly worked out It would appear that *M decumanus* is the species most commonly infesting ships although *M rattus* is also found

Sticker in his history of plague epidemics quotes the statement that *M decumanus* got into Europe from Persia about the year 1725 In England *M rattus* was displaced by the invasion of *M decumanus* about this time At the present day the predominating species in this country is undoubtedly *M decumanus; M rattus* is however becoming increasingly common in the seaports

An important question in plague epidemiology is the mode of conveyance of the infective organism from the plague rat to man It is impossible even to sum marize here the numerous experiments and observa tions on this subject but it may be said that from many sides and especially from experiments in the laboratory and in actual plague infected houses, a mass of evidence has been raised which incriminates and indeed convicts the rat flea as the transmitting agent of the infection

In India the rat flea *Loemopsylla cheopis* which closely resembles the human flea *Pulex irritans* in appearance is by far the most commonly found species In England the common rat flea is *Ceratophyllus fasciatus* a single specimen only of *L cheopis* has been found up to the present time

L cheopis especially if hungry will bite man *C fasciatus* does not take to man with any readiness but will undoubtedly bite on occasion This differen e in the appetite of the two species for human blood may be of significance in determining the likelihood of the spread of rat plague to human beings —*Nature*

PATENTS

INVENTORS are invited to communicate with MUNN & CO 361 BROADWAY NEW YORK or 625 F STREET WASHINGTON D C in regard to securing valid patent protection for their

Inventions Trade Marks and Copy rights registered Design Patents and Foreign Patents secured

A FREE OPINION as to the probable patenta bility of an invention will be readily given to any inventor furnishing us with a model or sketch and a brief description of the device in question. All com munications are strictly confidential Our HAND BOOK on Patents will be sent free on request

Ours is the Oldest agency for securing patents It was established over sixty five years ago

MUNN & CO., 361 BROADWAY NEW YORK
Branch Office 625 F STREET WASHINGTON D C

Trade Notes and Formulas

Soft Solder for Metal, Glass Porcelain etc —Pour over granulated zinc a solution of blue vitriol Of the solution 20 to 36 parts are mixed with sulphuric acid of 1 85 specific gravity and while stirring 70 parts of quicksilver added washing out well and cool ing When using heat the solder to about 707 deg F (75 deg C)

Weather Foretelling (Barometer) Flowers. —One hundred parts of chloride of cobalt 10 parts common salt 50 parts of gelatine 20 parts glycerine 200 parts distilled water The chloride of cobalt is dissolved in the necessary quantity of water the glycerine added then in this is dissolved warm the salt and the gelatine previously softened in cold water When cooled filter it and in it soak the flowers etc formed from uncolored material

Cements for Water Pipes —*a* Cement lute for cast iron water pipes 24 parts Roman cement 8 parts white lead 2 parts litharge 1 part rosin All to be p lverized and mixed and then worked up into a putty with old linseed oil to which half its weight, in rosin has been added and which has then been kept at boiling heat until all the rosin is dissolved *b* Equal parts of calcined lime Roman cement pot ter's clay and loam separately well dried finely ground mixed and kneaded up with linseed oil c. Rosin and tallow melted together and finely sifted plaster stirred in until the desired consistency is obtained

JUST PUBLISHED

THE SCIENTIFIC AMERICAN CYCLOPEDIA OF FORMULAS

The Most Complete and Authoritative Book of Receipts Published

Partly Based on the Twenty Eighth Edition of The Scientific American Cyclopedia of Receipts, Notes and Queries

Edited by ALBERT A. HOPKINS

Query Editor of the Scientific American

THIS is practically a ***new book*** and has called for the work of a corps of specialists for more than two years Over 15 000 of the most useful formulas and processes, carefully selected from a collection of nearly 150 000 are contained in this most valuable volume nearly every branch of the useful arts being represented Never before has such a large collection of really valuable formulas useful to everyone been offered to the public. The formulas are classified and arranged into chapters containing related subjects while a com plete index made by professional librarians, renders it easy to find any formula desired

"As Indispensable as a Dictionary and More Useful"

FOLLOWING IS A LIST OF THE CHAPTERS

I Accidents and Emergencies
II Agriculture
III Alloys and Amalgams
IV Art and Artists Material
V Beverages, Non Alcoholic and Alcoholic
VI Cleansing, Bleaching, Renovating and Protecting
VII Cements, Glues, Pastes and Mucilages.
VIII Coloring of Metals, Bronzing, etc
IX Dyeing
X Electrometallurgy and Coating of Metals
XI Glass
XII Heat Treatment of Metals
XIII Household Formulas
XIV Ice Cream and Confectionery
XV Insecticides Extermination of Vermin
XVI Lapidary Art, Bone, Ivory etc
XVII Leather
XVIII Lubricants.
XIX Paints, Varnishes, etc
XX Photography
XXI Preserving, Canning, Pickling, etc
XXII Rubber Gutta Percha and Celluloid
XXIII Soaps and Candles.
XXIV Soldering
XXV Toilet Preparations, including Perfumery
XXVI Waterproofing and Fireproofing
XXVII Writing Materials
Appendix Miscellaneous Formulas; Chemical Manipula tion; Weights and Measures, Index

IMPROVED FIRE HOSE NOZZLE THROWING 1¼ INCH STREAM

MODERN DELUGE SETS FOR FIRE EXTINGUISHING SERVICE.—[SEE PAGE 104.]

Gas Power Development: A Review

The Possibilities of an Important Prime Mover

By J R Bibbins, M Am Soc M E

AT the opening of the present century many were the prophecies of epochal development in all branches of the technical arts I believe the decade has fulfilled its promise First by way of comparison we find the steam turbine grown from 500 to 30 000 horse power with practice both in Europe and America gravitating toward a combination of the two principal types We find single boiler units increased from 300 to 3 000 horse power we find the steam engine then fully developed now endowed with a new lease of life through association with its erstwhile rival we find the electric generator literally decimated in bulk but still larger than its turbine

But returning to the field of gas power here too is measurable progress In size engines have developed from the single acting units of 100 horse-power or so to the double-acting tandem units of 4 000 or 5 000 horse power designed for and operating under the same conditions as steam equipment including the parallel operation of alternating-current generators We find the steel casting industry then comparatively undeveloped now able to turn out intricate one piece gas engine cylinders with jackets attached and crank disks with integral pins of the same material We find producer units developed from a diminutive 10 50 horse power up to 1 000 horse-power or more and the problem of bituminous fuels well along toward solution with practice tending in the direction of the induction type for both large and small units with self contained vaporizer and continuous service Opinion is somewhat divided as yet on the tar question but all efforts are directed toward the abolition of this undesirable by product by gasifying it

Industrial Applications —But in its varied applications the direct combustion principle has indeed achieved success It is obviously no exaggeration to say that the gas engine has made possible the submarine the aeroplane the motor boat and the automobile The aeroplane motor offers an object lesson in the results of high rotative speeds The 30 horse power motor of the Wright aeroplane weighs but 6 2/3 pounds per horse-power while the Darracq motor of about the same size built for the Demoiselle monoplane weighs 3¼ pounds per horse power The Gnome engine with radial rotating cylinders weighs still less

Concerning the much discussed problem of conservation I need only refer you to the utilization of blast furnace gas by product coke-oven gas by product oil gas from refineries and various low grade or by product fuels unused for steaming purposes A large power plant is now being built for using waste cupola gas which in heat value runs about 50 B T U and requires 300 pound compression The importance of these developments in solving the smoke problem and the power problem of our specialized manufactories and in deferring the national crisis—the extinction of fuel supply—cannot be overestimated

On the one hand by reason of its high efficiency the gas driven pump has found adoption in water works sewage disposal hydraulic excavation and long distance gas transmission On the other hand by reason of the absence of stand by losses it is equally desirable in emergency service such as fire protection auxiliaries with hydro-electric plants and for canal lock operation The coincident and related development of producers has brought about a revolution in such operations as hardening tempering melting soldering baking and cloth singeing and especially displacing the supposedly indispensable Bessemer converter with the open hearth furnace in single units of 100 tons or over

Gas Engine The development of the heavy duty double acting gas engine has been accompanied by certain interesting features which while not universal yet find quite wide acceptance in American designs Foreign center crank designs have been generally departed from in the use of the side-crank self adjustable bearing construction Experience has been gained with various cylinder materials all steel or all iron steel walls only cast iron liners both iron and steel pistons and with steel on steel The trouble predicted with the last does not seem to have materialized Krupp builds thin walls with longitudinal reinforcing tension rods while other foreign builders design cast iron walls as thick as three inches Dry metallic packing has been substituted for the elaborately water cooled style Fads in valve gear have disappeared, and the mechanism has been simplified by driving both inlet and exhaust valves from a single cam

Cyclic Governing Drop Principle —In early practice the regulator was quite generally driven from any convenient point along the cam shaft but now directly from or at a point close to the main shaft so as to avoid cyclic torsional effects in the cam shaft. Direct governing has largely been replaced by the relay type using drop cut-off or positive oil pressure to actually move the valves This has permitted the use of a very small regulator usually on the German straight line principle as represented by the Jahns & Hartung design, the weights moving directly against spring pressure Mixing is now done only at the inlet valves thus minimizing the result of a back fire By the symmetrical distribution of gas and air with reference to the four inlets non uniform mixing due to unequal fluid inertia effects has largely been overcome The electro-magnetic igniter has found much favor by reason of its simplicity and has made possible ignition at several points in the combustion chamber which has brought more rapid as well as surer combustion with lean gases A series system of circulation has reduced the water consumption and also the troubles from sweating of cold rods with high sulphur gas The foreign practice of cambering rods is entirely disregarded here for with light, one piece pistons the rod flexure is not greater than considered desirable to keep the sectional packing free And finally centralized continuous return lubricating systems are the rule for engine oil with timed force feed for cylinder oil This latter replaces all attempts at graphite lubrication or indiscriminate injection of oil during combustion

The special adaptation to direct connection to reciprocating compressors has brought about the variable speed long stroke gas engine (of two diameters or more) These are operated in the natural gas districts of the Central and Western States One company alone has twenty four of these units in service of about 1 300 horse-power each An interesting feature brought out by some recent tests by the author is that for the same power output the gas and heat consumption is not widely different at full or reduced speeds

A moderate size double acting engine has also come into use with about two foot stroke whose high rotative speed (200 revolutions per minute) is of great advantage in direct connected electric drive

The gas-electric motor car is another interesting development which has been under investigation for several years by railroads for service on extensions or suburban branches where regular steam equipment would not be justified These cars are self propelled by a compact eight-cylinder high speed generating set located in the cab and standard electric motor control Sixty seat coaches ordinarily make an average schedule speed of 25 miles per hour including stops Demonstration runs have resulted in a gasoline consumption of 36 to 48 gallon per car mile A single truck car of this type has been on trial for cross town service on some of the lines in New York city that have not yet been electrified

So much for progress and accomplishment The evidence exists throughout the land from the barking thousands of small engines upon the hillsides of the Pennsylvania oil fields to the great installations at Gary Buffalo and Pittsburg—in the Mexican highlands a central station burning mesquite in Texas using lignite in Canada peat—in the Nevada Ranges a mining plant with Diesel oil engines—in Nova Scotia and Buenos Aires other engines running rail road shops—in Ohio boosting gas to Cleveland—in Arizona watering the Imperial Valley reclamation—in Philadelphia and Coney Island providing high pressure fire protection—in Pittsburg operating the locks of the Ohio Canalization project This is admittedly a good record but we should never be guilty of that smug satisfaction that blinds us to minor shortcomings so let us glance at some aspects and causes of retarded development

RETARDATION

A very serious handicap in industrial work is the present inability of the gas-power system to supply means for factory heating in lieu of exhaust steam This is particularly serious in the northern states and in Canada. Unfortunately the high efficiency of the gas engine is lost when a steam eater' is desired in connection with a heating plant. Some progress is being made with the manufacture of exhaust heaters but the available 5 000 to 6 000 B T. U. per B horse-power is not sufficient for heating a large factory Some system of auxiliary gas-burning heater must be worked out with automatic temperature control to compensate for variations in load An attempt should be made at conserving this 60 odd per cent waste heat, now rejected in the exhaust so as to return the major part of it to the heat cycle

The gas engine is roundly scored for not having over load capacity for fluctuating peak loads Now with an efficient regenerating heater operating in connection with a low pressure steam turbine auxiliary it is possible to largely increase the output, or vice versa decrease the fuel consumption I am glad to report that one of our manufacturers is working along this line on a projected plant.

We must have more convenient and practical methods of measuring power gas both with respect to volume and heating value No sensible individual would attempt to operate a steam plant without a pressure gage even neglecting the personal risk, but with gas we are working continuously in the dark and with engines equally as sensitive as steam engines to reduced potential Some large plants have of course adopted the Venturi meter but even this simple apparatus is sensitive to deposits in the throat A continuous recording calorimeter is a great necessity and some progress is being made in that directions

There is a disposition to discount the demand for large units both engines and producers With turbine units increasing by leaps and bounds the gas-power industry must respond in kind if not in equal measure or remain an auxiliary for special conditions The 44 × 60 inch cylinder is now in evidence Let us have higher rotative and piston speeds with relatively shorter stroke and larger diameters if possible It is to be expected that the production of special high strength steels and further perfection of foundry practice will make this possible This improvement in engine construction will remove one of the causes of complaint in the past on large engines—the failure of cylinders and pistons—due for the most part to shrinkage strains

Nor can it be believed that the producer fuel bed has reached the limit of its diameter nor the maximum rate of gasification With a coal combustion of fifteen pounds per square foot per hour an eight-foot producer would yield only 700 B horse-power Marine and locomotive practice with induced draft succeeds with many times this rate A full grown power plant of to day requires units of 3 000 to 5 000 kilo-watt capacity with at least 2 000 horse power producers

Finally education not only of operator but of salesman and manufacturer is needed The last named is often the least wide awake, and the first the most receptive of intelligent guidance The great mistake is made in semi-education—first an incomplete understanding of the conditions second a make fit equipment third a jealous guarding of essential knowledge of defects The result is loss of confidence dissatisfaction failure When will we learn that to take the operator into our full confidence secures his allegiance for all time

THE FUTURE

Marine Propulsion —This most important development looms big on the horizon Much has been written of the producer gas system but it must be confessed that the oil burning engine is more attractive from the standpoint of convenience and compactness The advantage of storing oil in the ship's double bottoms is great from a standpoint of cargo capacity European countries have been active in this development, Russia with its tank ships, France with its submarines, and the coast countries with their fishing fleets. Successful producer-gas equipments are to be found on some of the inland water ways of Europe where coal is the cheaper fuel, and a boat is now being equipped here for service in New York Harbor

Recently has come the announcement of the adoption of oil engines for the 8,000-ton 12 5-knot freight boats now being built by the Hamburg-American Line These will be equipped with two 1,500 horse-power Diesel [illegible] built by the Augsburg & Nurnberg Works and if the experiment is successful similarly propelled passenger vessels will [illegible] structed One American builder, [illegible] up the Diesel engine for marine work.

Power From Crude Oil —The oil engine development seems to have made great headway abroad since the expiration of the basic Diesel patents. Two of

Chairman's address before the Gas Power Section, American Society of Mechanical Engineers New York December 1910

the principal companies have built together 250 000 horse-power with four and six-cylinder units up to 1,000 horse-power capacity per cylinder Small Diesel engines have been built from five to thirty horse-power The smaller engines are mostly four cycle, while above 1 000 horse power the two-stroke cycle prevails, which in an oil engine works out much more simply than in a gas engine where sep arate pumps are required for gas and air Maxi mum compression is somewhat over 500 pounds with air injection at 600 to 850 pounds In most cases the compressors are built into the main unit and geared Some of the builders are reported to be developing double-acting designs for engines of high power

In London one of the electric supply companies has installed Diesel engines using oil distillate to supplement the transforming equipment of its sub stations, at a cost per kilowat hour lower than that for the main stations A somewhat similar type of plant-operating in one of our eastern cities boosts the potential of low points in a direct current distri bution system The generators however are under compounded so as to limit the output and thus equal ize with other parts of the network Obviously the oil engine is an ideal prime mover for such service

In the various experiments with oil gas producers the small progress has been discouraging Two sys tem have been used the retort and the partial com bustion In the former difficulties with carbon depo sition in the retorts are encountered in the latter excessive production of lamp black Both are hope lessly low in efficiency as compared with the oil burning steam plants A large oil gas plant in Cali fornia operating gas engines as water power auxili aries endeavors to apply to power purposes mixed gas consisting of part retort and part carburetted water gas utilizing the carbon deposits of the former as briquettes in the latter process In this mixed gas the hydrogen content is kept down to about 30 per cent but in the oil gas it is very much higher 40 to 60 per cent For straight power purposes the combustion producer seems more promising both in simplicity and efficiency The Imperial Valley pro ject is being served by a small lift station of this type at Yuma Arizona

Power in the West Closely related is the de velopment of the Western power fields both for ir rigation and for mining operations The Easterner cannot realize to what extent irrigation has taken hold of the West and what a field there is for power pumping if it can only be developed Utah Arizona Texas and the Great Plains embrace broad areas underlain by basins or hardpan yielding ground waters at a depth varying from a few feet in favored areas to 50 to 70 feet in others At present electric power pumping is predominant John C Hays * in discussing a California installation men tions an area of 1 050 square miles 86 per cent of which is electrically irrigated He declares there is no reason why this field should not be open to gas power pumping One installation is already pro jected with gas driven generators but why not di rect pumping? No one familiar with the ever pres ent gas pumpers of the oil fields will fail to see the parallel But we must have a low priced engin simple fool proof and preferably of high speed multi cylinder type adapted to direct connection to centrifugal pumps Present types of high speed en gines are not really adaptable to rotary pumps be cause of the disparity between impeller proportions and engine speed although a few sizes can be found suited to low head work The new Humphrey gas pump is evidently well suited to this service In fact some of these pumps are now operating in irri gation enterprises in India Recently a unit as large as 25,000 000 gallons has been contracted for This pump utilizes the water column itself as a piston and is approximately fool proof

A crude oil engine is obviously a necessity in the Far West East of the Rockies lignite suction pro ducers in small sizes would find application but in California, oil predominates In 1908 the oil produc tion in California was 48 300 000 barrels at an aver age price of $0 54 per barrel The majority of this was asphaltum base oil 12 deg to 17 deg Be

In the mining districts we find wood charcoal and black lignite used for steaming purposes even where water is scarce and impure One plant, however ac cepted the situation and installed Diesel engines with a continuous, closed, fan-cooling system for jacket water

The development of lignite deposits in the Middle West is encouraging In 1907 the output west of the Mississippi was 5,000,000 tons of which Colorado produced one third, with Wyoming and Texas next in rank, with an average price of $1 55 per ton as com pared with $1 12 for all bituminous coal mined in this country This price does not, of course, apply to the more inaccessible regions, where fuel costs $4 to $8 per ton Here in the West is an opportunity

Canada—We have looked to Canada for important developments in the use of peat, but private experi ments have failed so signally that the government has started a peat manufacturing and power plant to demonstrate the process on a commercial scale and re establish confidence in this industry Director Haanel of the Canadian Bureau of Mines thus summarizes his investigations Artificial drying processes have failed commercially and a machine process must be substituted for the manual labor The department is therefore proceeding along European lines of es tablished success He states that Russia alone pro duced 4 000 000 tons of peat fuel in one year 1900 Peat containing not over 25 to 30 per cent water has been found an ideal fuel for gas producer work It requires no further vapor and is quite free from high temperature and clinker The long series of fuel tests at Montreal have served to confirm the results of our own government's tests on lignites in demon strating the great possibilities of these lignite deposits especially in the Canadian Northwest

Self Starting Engine No real progress is ap parent in the self starting gas engine Some automo biles are equipped with small compressed air motors but at considerable expense No simple combustion method has yet appeared The opportunity is clear On very large units one builder employs for start ing an explosive mixture compressed to about 80 pounds and stored in the same manner as the usual compressed air Some trouble has been experienced in guarding against back fires into the storage tank

Double Deck Stations—In large cities where land is dear a new style of power plant would seem to have some possibilities viz the double deck type with the produced plant above This has some ad vantages over the familiar double-deck turbine plant in that the steel work of the building would be de signed for a dead load concentrated along the sup porting walls where the producers would naturally be located I am not sure of the comparative costs but the economy in spa In a large plant works out relatively low

Engineering Economics Returning now to a consideration of some of the broader aspects of this subject it seems to me that there are some fruitful fields still undeveloped Engineering to-day has be come not entirely a technical but an economic sci ence as well We must not only ask the question Will it work? but first and foremost Will it pay the proper return on the investment? Consider for example the total cost of power production How much earnest effort has been thrown away in fruit less discussions of mere operating costs technical finesse when the language of fixed charges depreci tion obsolescence super cession and business risk had not fully been learned This phase of gas power de velopment has been of serious consequence in the past and undoubtedly responsible for many of the fail ures on record Such problems continually arise in the course of comparative studies of gas producer and turbine plants with various load factors and prices of coal The success of the by product coke oven industry in realizing profits from its by products rests solely upon the economics of the case and abruptly raises the question Which is the major product gas or coke? The analysis of the cost of production is of far more importance than that of microscopical improvement in efficiency

Technical Consular Attaché—No one can deny the great value of detailed knowledge of the develop ment of the arts in foreign countries Private in dividuals or corporations constantly invest large sums in securing such information for their purposes Now in view of the extended activity of our govern ment along scientific and commercial lines as evi denced by the Geological Survey the Bureau of Mines the Bureau of Standards and the Smithsonian Insti tution does it seem unreasonable to broaden the use fulness of our consular service by the establishment of a new function a technical investigating staff whose duties would be to keep constantly before American engineers the more important achievements of for eign contemporaries? The excellent report on Peat and Lignite by the Canadian Bureau of Mines is a case in point The fact is that progress to-day is so rapid that no individual can hope unaided to keep abreast without expending time in general investiga tion that should properly be detailed to special talent And it seems to me that the national engineering so cieties should be the leaders in fostering this activity

Co operative Research—The movement toward the co-operation of the engineering fraternities with the educational institutions should be encouraged first by the more widespread establishment of technical ap prenticeships in our shops and offices It is no ex aggeration to assert that to-day the technical grad uate furnishes the new blood of industrial enterprise His training and his ideals form the ground work of a steadily improving standard in commercial life By the same token the colleges have a right to ex pect co-operation Their costly laboratories are at our disposal for the asking We spend millions in commercial experiments that can at least only yield approximations Many of these investigations should be transferred to the laboratory

There is now before the technical institutions of the country a comprehensive list of subjects need ing scientific investigation many of them of the ut most importance Could we persuade the manufac turers of the country to endow graduate fellowships in their chosen fields with ample funds for defray ing the material costs of such investigations the re turn on their investment I believe would be well above the market rate of interest A few pro gressive concerns have taken this step but they may only be regarded as a precedent One technical in stitution has itself provided an endowment

Interest the student in your business by affording him some incentive and he will become a loyal ap prentice an effective salesman and a competent ex ecutive I beg to suggest that this section take more definite action through the society along these co operative lines As subjects I need only mention the following as typical Are there any manufac turers interested?

(a) Maximum efficient rate of combustion in pro ducers as affected by width and depth of fuel bed rate of blast moisture content and character of fuel

(b) Study of chemical reaction in the fuel bed to determine the conditions for suppressing the form tion of tar or lamp black and securing maximum percentage of combustibles in gas together with high overall efficiency

(c) Study of the relative jacket absorption with varying time contact due to different combustion chamber and cylinder proportions and piston speeds

(d) Effect of auxiliary precompression of charge on efficiency and power of gas engines with refer ence to securing unlimited overload capacity

(e) Determination of the most suitable form of gas engine indicators to standardize accurate meth ods of working

(f) Research work on maximum heat values of combustible mixtures standardizing formulæ for the standard reference cycle

Work of the Section—Finally as to the work of the Gas Power Section The interest manifested in the last few meetings indicates that it has been pro ductive of results Out of 180 papers presented to the society within the last five years twenty four have been devoted to gas power or related subjects two committees have presented comprehensive re ports and a third committee its detail work from time to time Although none of the committees now at work have reported conclusively their preliminary reports have furnished ample basis for further action Possibly the most pressing need is the standardization of tests and efficiency determinations These matters were brought to the attention of the society in con crete form by the standardization committee of this section and are now in the hands of the power test committee of the society

The greatest value therefore of the section rests in the contribution to the art in the papers or reports presented We should not glory in mere numbers but on the other hand excessive concentration in the choice of subjects does not effectively reach the full membership We may well accept the two contribu tions on blast furnace practice as an earnest of our desire for contributions of the highest possible stand ard I have heard Lord Bacon quoted on this theme I hold every man a debtor to his profession from the which as men of course do seek countenance and profit so ought they of duty endeavor to be a help and ornament thereto This seems sound doctrine and in the belief that it will not fall on arid ground I look for the continued growth of this membership with the very keenest interest

* American Institute Electrical Engineers May 1910, The Mount Whitney Power Co.

Although the home of the tin plate and sheet mills South Wales is hardly an important center for the manufacture of ordinary steel rolled sections or of pig iron it is now stated that two new steel works at Barry in South Wales are in contemplation as well as another at Irlam on the Ship Canal According to published statements the larger of the two Barry schemes will be very complete and will embrace blast furnaces and steel works for the production of sheets and heavy rolled sections The other works is ex pected to specialize in heavy rolled sections The Irlam works like the Barry schemes will depend largely upon imported raw materials anyway upon water borne materials except as regards fuel Middles brough and the Clyde districts cannot be expected to welcome these new additions to the steel industry It is to be noted that other recent additions to British iron and steel industries have shown a disposition to situate themselves in other districts more especially Lincolnshire and South Yorkshire

The Improvement of the Flying Machine

To the Editor of SCIENTIFIC AMERICAN SUPPLEMENT

Recent events in the science of aerodynamical flight have followed preceding flying feats with so marked an advance that to the layman it would appear that the true subjugation of the air is accomplished beyond dispute. Yet to the impartial student of natural and artificial flight it cannot honestly be conceded that progress with mechanical flying machines has justified the belief that it is commensurate with the vast number built and experimented upon. Indeed the skill of the pilot has progressed more than the improvement and evolution of the machines. It is the object of this article to consider precisely the question of both natural and artificial locomotion in the air, and to analyze recent experiments on the one hand with their obvious faults, and on the other demonstrate those superior qualities enjoyed by Nature's machines whereby they excel man in the real conquest of atmospherical space. From the analysis it will be shown that there are neither subtle mysterious laws nor inscrutable mechanics in nature as exemplified in the volant bird, bat, or insect that cannot be faithfully reproduced by the methods and intelligence of man, and that in comparison with the feats of the bird he not only accomplishes them but actually surpasses them.

Without describing exhaustively the structure and the infinite number of designs discovered in the animal kingdom, it may be remarked that the earliest known flyer is the extinct pre-historic pterodactyle (*Pterosauria*), wing-fingered specimens having been found in their fossilized form in the cretaceous rocks of America and England with membraneous wings 25 feet span. In striking contrast is the tiny *Diptera* or two-winged, with microscopic-sized rudimentary posterior wings or halteres which act as balances in flight, seen in the house-fly, wasp and bee. To this order should be added *Coleoptera*, comprising the beetles; *Hymenoptera*, butterflies and moths; *Adonata*, the wonderful dragon-fly; *Cheiroptera*, the bats; and

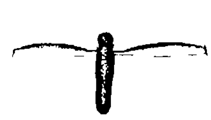

Fig. 1.—The Insect's Wing Traveling in Horizontal or Waved Figures of 8 Line of Progression Shown by Dotted Lines.

lastly the countless designs observed in the perfection of flight, the true aeroplane, the bird. Varied in structure and contour though all may be, it is significant that *all* fly on one and the same principle—or possess the power to accomplish it—that of the screw. Innumerable in variety, some being falcated or scythe like, others oblong or rectangular, others rounded or circular, while others again being lanceolate or linear, the fact remains that whereas the *designs* need not be restricted in number the main principles and agencies underlying the same must not be departed from if the conquest of the whirls and eddies of air is sought. Note therefore that there must be neither divergence nor departure from natural laws. *A thorough knowledge alone will enable us to design fundamentally and construct a true flying aeroplane.*

Hence without unduly enlarging on structural points in nature, we know as demonstrated by Pettigrew's life work that the wings of birds, bats, and certain insects are of helicoidal curvature with a certain concavo-convexity of form near the shoulder, while all are semi-rigid anteriorly and flexible posteriorly and toward the tips, also graduating in thickness from the root and tapering to a fine plastic point at the tips, which enable the pinions to be automatically stable when encountering opposing winds or those of a vertical tendency, and consequently conferring those fine qualities which react upon the air with such efficacy in obtaining the maximum of horizontal displacement or support while securing a minimum of resistance in flight. They form both structurally and functionally reversing screw propellers, one primary feather in fact being equivalent physiologically and morphologically to one whole wing.

It is however the following points that the writer wishes to enhance, as they constitute the key to the whole problem of success and are the true dogma and distinguishing feature whereby the subjugation of the air *must* be accomplished. Wings, besides being structurally and functionally powerful propellers, sustainers and elevators of remarkable efficacy when beaten in helicopteral flight in forward translation, have their sail area of apparent inefficient dimensions, and one would imagine wholly incapable traveling surfaces. Quite so. Yet Nature, foreseeing that in order that her children should subdue and not be subdued, increases the sail area by bewildering rapid motions or beats, thus augmenting the dimensions and creating *solid bases of support* by superior speed, perfected traveling surfaces designed to satisfy the resiliency of the air and the inertia of the mass of the flying animal, and superior power residing in the powerful pectoral thoracic muscles. Slight though these may be in comparison to the enormous weights and motors of man, there is no gainsaying the fact that natural machines soar in winds and accomplish feats we have hitherto failed in, thus furnishing a practical demonstration that the *whole wing-area is utilized* to con-

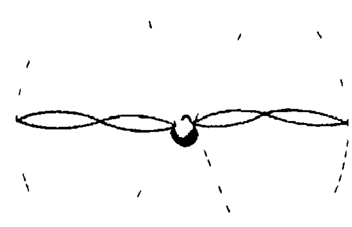

Fig. 2.—The Effective Sustaining Area Due to the Sweep of a Bird's Wings.

summate the triple function of propelling, sustaining and elevating the flying creature. Figs. 1, 2 and 3 illustrate this principle concisely, the first showing the insect's wing traveling in a horizontal path or a waved figure-of-8 line of progression as shown by the dotted lines, the second representing the bird, the last illustrating the screw propeller of man reproducing precisely similar principles and results in rotation in a circular path against the reciprocal motion of the bird and the insect. Here then is the first simple triumph and improvement mechanically furnished by Man over Nature, i. e., the transference of reciprocating into rotary motion.

Accepting the bird as the ideal aeroplane model, we find that steering at right angles and horizontal movements present little difficulty and are accomplished in a variety of ways. A bird flying diagonally through the air attains its maximum of support or pressure at the front edge of the wings; increase of velocity tending to thrust up the anterial margin, the bird counteracting this by accommodating its center of gravity farther forward, backward, or raising and lowering the same in accordance to conditions. This is secured by (1) raising the wings in a dihedral angle above the body, resulting in lowering the center of gravity; (2) flexure of wings against the body, thus bringing the same farther forward; (3) throwing conversely the wings forward and so correspondingly reversing the conditions; or by (4) extending the head and neck as in the case of the pelican, stork or flamingo, and spreading the tail. Steering is effected either by (1) raising one while depressing the other; (2) diminution of the parachute area of either wing; (3) twisting the pinions into an helicoidal curvature, which principle is that copied by the Wrights and confiscated by all other aeroplanists; (4) or by raising and lowering each side of the tail. Compare the varieties of movements and capabilities with the superior qualities of flexible construction of wings and latent power to beat them against the inert immobile and passive sail area of the aeroplane, which can readily be detected. In Fig. 4

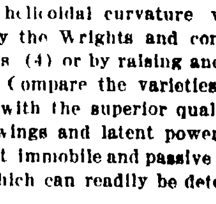

Fig. 3.—Screw Propeller, the Dotted Line Gives Projected Area.

is shown in section an ordinary Blériot type monoplane of some 30 feet span, with the usual 6 feet 6 inches tractor in the center. The insufficient active surface of the same is portrayed by the dotted lines, clearly demonstrating the poor comparison of active *versus* passive sail area, the latter predominating in excess as against Nature's examples where the *whole area is utilized*. If, however, the aeroplane surfaces are constructed with flexible tips and posterior margins, and twin screws are employed of twice the diameter of propellers, it will immediately be recognized that these superior qualities seen in the bird are greatly enhanced and ability to fly in stronger winds is attained by simple means. As an illustration of the inability of the modern aeroplane lacking adequate means of conquering adventitious currents, the writer quotes from the report of the Blackpool aviation meeting in England, from an aeronautical contemporary: "Owing to the strong winds varying in velocities, no aeroplanes ventured out from their sheds even, and the only aviators seen aloft were the sea-gulls, and *they* flew all day long."

Thus the incontestable fact remains that although certain aviators like Latham, Paulhan or Johnstone have flown by superior skill in winds which others dread, it is for a brief period only, while the slight power residing in the muscles of the gulls, compared with the 50 to 120 horse-power and great increase in the mass of machines weighing from 600 pounds to nearly a ton, sufficed to enable the bird to beat man's efforts at subjugating the air by simply adopting well defined proven laws instead of copying others' faults as man is content at present to do!

From the foregoing remarks, which are briefly subtracted and amplified from the lecture given by the writer entitled "Flying Ships of the Future" in 1908 at the Royal United Service Institution, Whitehall, England, it will be conceded without prejudice that a remarkable co-relation exists in the laws of nature and the improved flying machine built by man. Indeed, in order to prevent repetitions of fatal accidents with the modern *incomplete* aeroplane, the cause is not far to seek, as the foregoing lines demonstrate in the remedy presented. The world is asking for enlightenment in this respect, but how correct are the explanations? Certainly not by constructing the traveling surfaces of the aeroplane wings more rigid, heavy and inert. No. Flight by mechanics is the product of superior inertia, volition, power, and *properly constructed* traveling organs or wings, and there can be no question that under such conditions machines embodying these requirements will afford a veritable example of *multum in parvo*, and will make flights around the world over sea and land perfectly feasible. Given adequately powerful reliable engines, improved traveling surfaces, either rotary or reciprocal, and *whose active area predominates*, whereby is elicited a responsive upward and forward recoil on the air instead of inert passive surfaces seen in the present aeroplane,

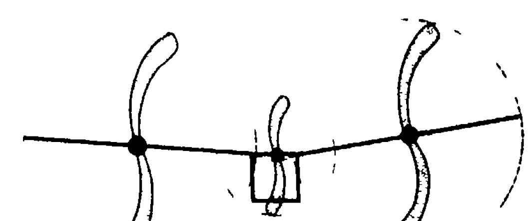

Fig. 4.—Section of Blériot Monoplane. Dotted Lines Show the Passive Compared with the Active Sail Area of Birds and Insects.

the perfected yet simple airships with these essential features will literally forge itself with the potential aid of gravitational energy and the immense inertia of the dynamic mass through all resistances of wind tending to deflect it from its path, thus ensuring the *true subjugation of the air*.

Pimlico, London. EDGAR E. WILSON.

Guns in Mine-laying Vessels

THE question of providing suitable gun arrangements for mine-laying vessels is, it is reported, engaging the serious consideration of the British Admiralty. This valuable type of auxiliary vessel has as the result of the trials and experiments carried out since its inception developed into a single independent unit. Being self-contained and therefore ready at all times to act on her own initiative, she can select the most suitable time as regards weather conditions and also take the best route to proceed as rapidly as possible in order to achieve her object, namely the blocking of a possible enemy's port. This line of development has of necessity taken her farther and farther from the original conception of her duties, which was to act as one of a group of similar vessels under the protection of an escort of cruiser or battle units. This change has rendered the question of her protection against possible attack when moving to and from the danger zone one of vital importance. In the case of the "Intrepid," recently converted for use as a mine-layer, it has been decided to provide her with an armament of 6-pounder quick-firing guns. This is, however, felt to be only a tentative measure, as these excellent little guns are now quite outclassed by the improved armament of 4-inch and 12-pounder, or their equivalent in foreign navies, which are now mounted on modern destroyers. In circles competent to judge it is considered that a small mixed armament of 4.7-inch—of which there are a large number in reserve—and 12-pounder quick-firers would be an ideal armament for this class of vessel, or at least nothing smaller than 12-pounder guns should be included.

The Gas Turbine*

A Consideration of Proposed Types

By A W H Griepe

It is generally recognized that one of the chief difficulties in the way of devising a practical gas turbine is to find a material for the vanes which will be capable of withstanding the effect of being in contact with gases at the high temperatures produced by combustion

Properties of Gasoline and Air

Test Number	Mixture Volume		Time in Second Between Ignition and Highest Pressure	Explosive Force in Pounds per Square Inch			Temperature of Combustion in Deg Fah	Temperature of Combustion in Deg Fah
	Gasoline Vapor	Air		Compression of Air in Pounds per Square Inch				
				42	5	1	Actual	Theoretical
1	1	18	(28	150	208	261	1877	3545
2	1	11	0 18	183	244	307	2198	4010
3	1	9	0 18	234	316	390	2403	4806
4	1		0 07	261	348	435	3119	6001
5	1	5	(05	270	300	450	3259	6951
6	1	4	0 07	240	320	400	2965	5 1

* At atmospheric pressure

The actual temperature of the gases however though high does not approach the theoretical temperature as is shown in the table the figures of which they obtained in laboratory tests made by Dr Richard Wegner of Heidelberg Germany

Forcing steam or water into the rotor to cool the blades has been suggested as a means of preventing their destruction by the high temperature gases This arrangement to be effective would no doubt complicate the construction of the turbine considerably and would probably reduce its efficiency

An excess of air in the mixture has also been suggested as a means to this end The effect on the explosive force of the mixture is clearly shown in the table Several attempts have been made to use blades made of heat resisting materials such as quartz and slate etc Hard porcelain reinforced by wire mesh has also been tried but with very little success

Blades made of vanadium steel and covered with a layer of magnesia have shown the best results so far but have not proved sufficiently good to warrant the use of this combination

Fig 1 represents diagrammatically a gas turbine of the velocity stage type coupled to a three stage centrifugal air compressor as proposed by Dr Stolze† of Charlottenburg and described in a paper read several years ago The gas which is controlled by the flyball governor enters the explosion chamber under pressure and is mixed there with air (under pressure from a three-stage centrifugal air compressor) The mixture is fired in the chamber after which the air and hot gases expanding in the nozzle enter the turbine where they give up their energy in much the same manner that steam does in the steam turbine passing the rotating and stationary blades on their way to the exhaust outlet

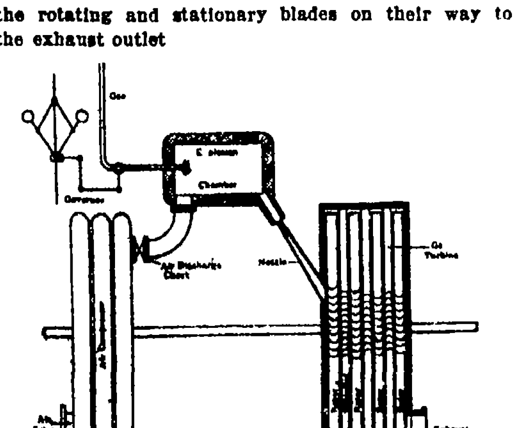

FIG 1—DIAGRAM OF STOLZE'S PROPOSED TURBINE

An improvement has been proposed for this type of turbine unit which consists in forcing steam or water into the combustion or explosion chamber in order to reduce the temperature of the burning gases to a temperature that will be safe for the vanes

Fig. 2 is a more or less diagrammatic sketch showing an elevation and cross-section through a reaction type of turbine proposed by Dr Wegner and described in a paper written two years ago

* From Power and the Engineer

† This arrangement is attributed to Rudolf Barkow by Mr Supino in his book "The Gas Turbine."

The turbine rotor is made up of four tubes closed at the outer ends and flanked on each side by round plates as indicated These plates are provided with circular openings which admit air for cooling the tubes after each explosion (See the elevation) The tubes and plates revolve on a shaft in the direction indicated by the arrow

At the outer end each tube is a De Laval nozzle and near the center of the hub are two openings axially opposite each other for use in the admission of gas and air both openings being guarded by check valves The gas check valve as will be noted is connected to a ring which passes in front of a segment with a circular opening which admits the gas

A spark plug is attached near the outer end of each tube as shown in both views

When passing by the gas admission segment each tube is filled with gas and air through the check valve ports The gas is under a higher pressure than the air and therefore forces the air check valve to its seat and as the turbine revolves further the centrifugal force compresses the mixture in the outer ends of the tubes The spark plugs then ignite the mixture after which the hot gases escaping under pressure through the De Laval nozzles force the turbine to revolve in the direction opposite to the outflow of the gases

After the explosion occurs the check valves open again admitting cool air which clears the tube of the burnt gases at the same time cooling the tubes As

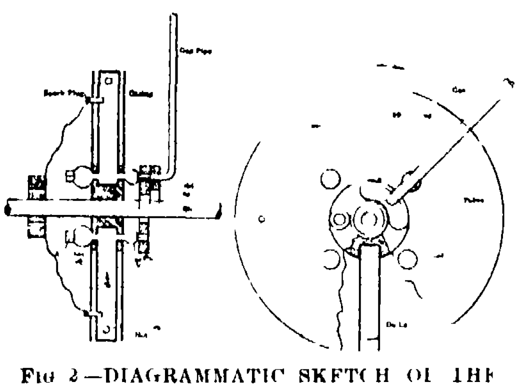

FIG 2—DIAGRAMMATIC SKETCH OF THE WEGNER PROPOSED GAS TURBINE

the casing and tubes revolve air is sucked in through the cooling air inlets (shown in the elevation) which further facilitates the cooling of the tubes after each explosion

Four explosions occur for each revolution of the turbine and the reaction of the outflowing gases against the atmosphere is the source of the power

The turbine is therefore a reaction turbine in its simplest form making separate air compression unnecessary

THE GRIEPE TURBINE

Figs 3 and 4 show a gas turbine designed by the writer which is really a combination of the gas engine and gas turbine The unit consists of the turbine a three stage centrifugal air compressor an air accumulator and a gas chamber The whole unit is set on a common base which is built out as an exhaust chamber

As will be noted from the following description the flow of hot gases against the blades is intermittent

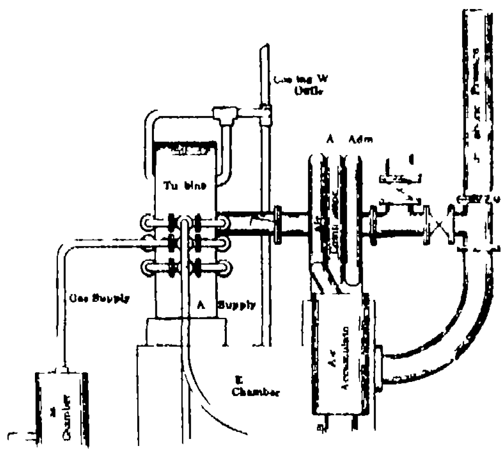

FIG 3 COMPLETE ARRANGEMENT OF GRIEPE'S PROPOSED GAS TURBINE UNIT

which gives the blades time to cool somewhat between the moments when they are in contact with the gases

The rotor A (Fig 4) which is shown in black is made up of a series of expansion chambers containing blades B and a series of closed compartments C which separate the expansion chambers The rotor A carries a ring D having openings E to admit gas from the gas chambers to the explosion or combustion chambers F

Contact pieces G fastened to the rotor close the electric circuits of the spark plugs which are located in the walls of the explosion chambers Explosion chambers are provided on both sides of the rotor web but are staggered angularly to avoid dead positions

The main structure contains compartments for compressed air cooling water and gas as shown

The explosion chambers F are located on the outer part of the central structure and are alternately closed and opened to the expansion chambers by the inner faces of the compartments C The explosion chambers may be as shown or carried completely around the circumference of the central structure according to the size and power of the turbine

Compressed air from the compressor passes through the four way valves K which act as injectors The air draws a certain quantity of gas along with it while passing through the valves and the mixture is forced

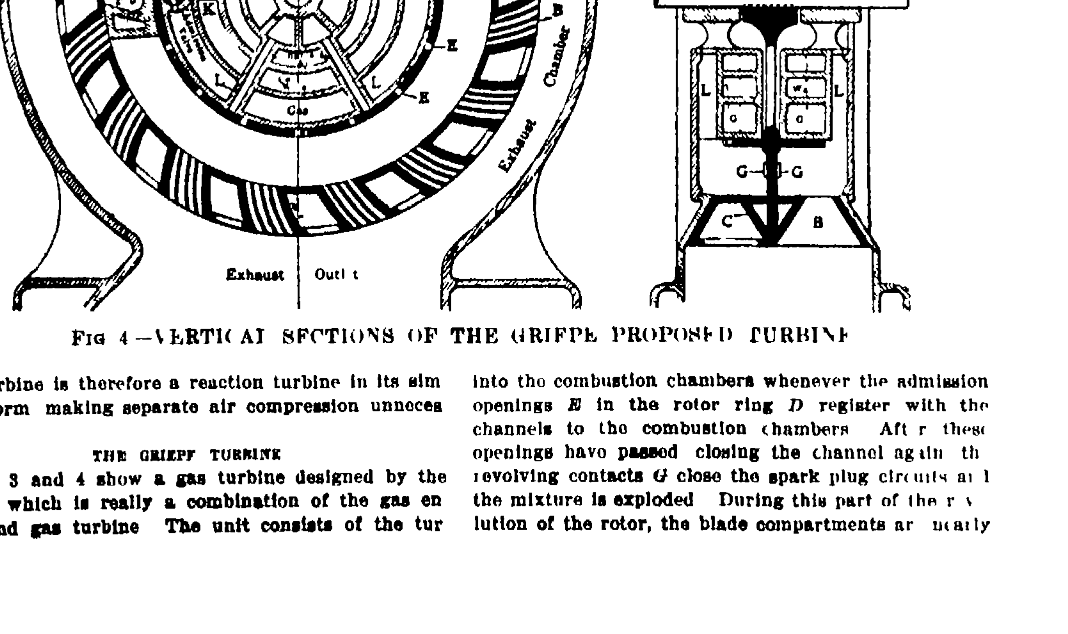

FIG 4—VERTICAL SECTIONS OF THE GRIEPE PROPOSED TURBINE

into the combustion chambers whenever the admission openings E in the rotor ring D register with the channels to the combustion chambers After these openings have passed closing the channel again the revolving contacts G close the spark plug circuits and the mixture is exploded During this part of the revolution of the rotor, the blade compartments are nearly

opposite the explosion chambers and an instant later they register and the gases escape through the vanes forcing the rotor in the direction of the arrow Further motion of the rotor brings the compartment C again over the openings of the combustion chambers and the cycle is repeated

In the design shown here it is evident that the vanes or blades *B* are not continuously in contact with the high temperature gases, as during three-quarters of a revolution of the rotor the blades are surrounded by gases at a lower temperature cooled by air admitted through the air channels *I* into exhaust chamber

The centrifugal air compressor driven by the turbine discharges into an accumulator to insure uniform air pressure The density of the explosive mixture of gas and air can be regulated by adjusting the air pressure

A further change in the output of the turbine can be attained by opening or closing one or more of the four way valves *K* thus changing the number of explosion chambers in action

Production of Low Temperature and Refrigeration—I*

The First International Congress of Refrigerative Industries

By L Marchis

The first International Congress of Refrigerative Industries held at Paris October 5th 12th 1908 was remarkable for the number and importance of the papers submitted by the men of science and engineers who responded to the call of the organization committee

The congress was divided into six sections as follows

First section Low temperatures and their general effects

Second section Refrigerating media

Third and fourth sections Application of refrigeration to food and in various other industries

Fifth section Application of refrigeration in commerce and transportation

Sixth section Legislation

In this article we do not intend to summarize the memoirs and communications presented but rather to give a general view of the congress that brought together men of science engineers biologists legislators and men from the business world

I LIQUID AIR AND THE PROPERTIES OF BODIES AT LOW TEMPERATURES

The first section considered principally the production of liquid air and the preparation with this as a starting point of oxygen and nitrogen in a commercial way

It is well known that air like all gases is brought into a liquid condition by the combined effect of lowering its temperature and expanding it sufficiently In carrying out this process gaseous air cooled to a low temperature is expanded suddenly from a pressure p to a lower pressure p Part of it goes over into a liquid state and the other part gaseous and very cold is led into an economizer where it cools down the air that is being compressed to the pressure p for the first time

The essentially adiabatic expansion of air can be effected in two different ways

(*a*) Air compressed to the pressure p may be expanded without doing available exterior work It passes from the compression tank to the liquefaction tank by the way of a narrow orifice This is the manner of expansion adopted by Linde in his liquid air machines The lowering of temperature obtained under such conditions is only appreciable if the difference between the pressures p and p is considerable In Linde's apparatus† gaseous air cooled to about 100 deg C is expanded from a pressure of 200 to 40 atmospheres the liquefied part of the gas at about 140 deg C passes into a regenerator where it cools the air compressed at 200 atmospheres It is then led into a pump which brings it up to this latter pressure A second auxiliary pump draws air from the atmosphere to take the place of that part which has been liquefied In the industrial machines the gases compressed to 200 atmospheres before passing into the economizer where the gas at —140 deg C circulates are cooled by liquid ammonia

Under such conditions in machines which produce 0 liters per hour the yield of liquid air is about half a liter per horse power hour

(*b*) The second method of air expansion consists in utilizing the exterior work which the gas is capable of doing when it passes from pressure p to p This mode of expansion with utilizable exterior work is the basis of the processes of G Claude for the production of liquid air‡ Air compressed to a maximum pressure of 0 or 40 atmospheres passes first to an economizer where it is cooled down as in Linde's apparatus by un liquefied gas It is then expanded in the cylinder of a motor whose energy can be utilized in the original compression of the air In course of time a partial liquefaction of the air occurs in the cylinder of the auxiliary motor The lubrication of this cylinder is accomplished by means of a petroleum distillate having a specific gravity of 0 675 (automobile gasoline) which at the low temperature at which the motor operates attains a sirupy consistency comparable to industrial lubricants

Applied in this form the process of G Claude gives only unsatisfactory results The expansion of the air occurring at temperatures of —175 deg to —180 deg by the gas expanding in the auxiliary motor takes place under unfavorable conditions The appearance of liquid air in this auxiliary cylinder is likely to produce a peculiar water hammer effect and is accompanied by a large increase in friction that is to say by a correlative destruction of the liquid air produced Moreover under the most favorable conditions the yield of this machine is hardly more than 0 2 liter of liquid air per horse-power hour

For this reason M Claude has been led to modify the process in the following way which I shall endeavor to explain A part of the cooled current of air compressed to 40 atmospheres is deflected before it arrives at the expansion cylinder This air under a pressure of 40 atmospheres is led into a chamber (liquefier) cooled by the gas of the original current which has been expanded in the auxiliary motor Thanks to a pressure of 40 atmospheres the deflected gas is liquefied in this latter chamber at a temperature no longer of 190 deg C as was the case in the original process where liquefaction occurred at the limit of its expansion but at — 140 deg C Further more the expanded air which circulated in the liquefier is heated up and arrives in the economizer no longer at 190 deg C but at about —130 deg C It cools the gas in the feed conduit less so that this gas arrives in the auxiliary motor at a temperature of about —100 deg C Its expansion takes place therefore under more favorable conditions and liquefaction by expansion is less to be feared

By thus substituting liquefaction under pressure for spontaneous liquefaction by expansion M Claude had brought his process of recovering the energy of expansion down to a practical basis With machines utilizing an exterior air compression capacity of 75 horse power the yield of this process becomes as high as 0 7 liter of liquid air per horse power hour

This idea can be carried still further however The air which arrives at the auxiliary motor at a pressure of 40 atmospheres and a temperature of about 100 deg C can be subjected in expansion to a too great drop in temperature To avoid the recurrence here of the difficulties encountered in the original process all that has to be done is to carry out the expansion by degrees in several auxiliary cylinders The air of the first expansion can circulate about a first liquefier into which is led a deflected portion of air from the feed circuit in a cold and compressed condition The circulating air is warmed up and goes on to be expanded in a second auxiliary cylinder This air from the second expansion is sent into a second liquefier similar to the first and is finally led into the economizer In practice the two liquefiers are not distinct the two currents of air after expansion merely circulate about different sections of the same liquefaction apparatus M Claude has given the name of compound liquefaction to this last process It marks a new and important step in the technique of the liquefaction of air In machines of the type described above the yield of liquid air by the application of compound liquefaction is as high as 0 85 liter per horse power hour

Liquid air promises to be the sole industrial source of oxygen and nitrogen The manufacture of these two gases at a very low price is a problem the solution of which has a very great importance in metallurgy and in the fertilizing industry How we can derive these gases from liquid air is a problem that I am now going to consider

Oxygen and nitrogen are two bodies whose critical points are slightly different (—118 deg C and 18 atmospheres for oxygen —146 deg C and 33 atmospheres for nitrogen) The vapor tension curve of nitrogen is below that of oxygen At a like temperature, below the lower of their critical temperatures the two gases, considered separately, liquefy at very different pressures The liquefaction of air—that is to say, a mixture of these two gases—presents, however some peculiarities which are worth mentioning

If at a sufficiently low constant temperature, T, air is compressed in a closed chamber the following phenomena may be observed

(1) At a predetermined point of pressure P_0, a first drop of liquid appears This is what after Duhem,* we call the dew point

(2) If at the constant temperature T the volume of the air is diminished the pressure increases at the same time the quantity of the liquid phase grows larger If this increase of the pressure is continued all the air will pass into the liquid state the values for P and T for pressure and temperature at that instant characterizing what Duhem has denoted the boiling point

(3) The dew and boiling points obtained at different temperatures trace in the system P O T on one hand the dew line and on the other the line of boiling of the gaseous mixture considered

(4) For each system of values (T P) of temperature and pressure the two phases liquid and gas are in a state of equilibrium in this state the composition of the two phases is different

(5) The percentage of oxygen (the more easily liquefied element) in either liquid or gaseous phase we will term the content of this phase

The content of the liquid phase in a sate of equilibrium is always greater than the content of the gaseous phase At a constant temperature when the pressure is increased the contents of the two phases liquid and gaseous continue to diminish till the mixture is completely liquefied Thus when air is liquefied (volumetric content 21 per cent oxygen) the first drop of liquid contains oxygen and nitrogen and its content is 47 per cent This content continues to diminish as the volume of the liquid phase increases A liquid with 34 per cent oxygen can only be in equilibrium with gas of 12 F per cent oxygen But as long as there is a gas phase its content is considerably above zero C It remains above 7 per cent

It can be readily seen therefore that if the two phases liquid and gaseous formed by the progressive liquefaction of air are maintained in contact it is impossible to prepare gaseous nitrogen of a sufficient degree of purity

It is a different matter however when under constant pressure conditions the liquid phase is eliminated as fast as it is produced We find ourselves here in the presence of a phenomenon inverse to that observed when liquid air is distilled under constant pressure In such a case the contents of gaseous and liquid phases increase continuously The phases both tend toward a composition of pure oxygen At the same time the temperature of boiling rises from a value in the neighborhood of that of pure nitrogen to the boiling point of pure oxygen Inversely, if we progressively condense air under constant pressure eliminating the liquid phase as fast as it is formed there are obtained gaseous residues less and less rich in oxygen at the same time the temperature of condensation becomes lower and tends toward the boiling point of pure nitrogen at the pressure employed We obtain therefore much more rapidly than in the process considered above a gaseous mixture richer in nitrogen To obtain a gaseous residue practically free from oxygen however it is necessary if this method is used to almost completely liquefy the air

A much better result is obtained by the use of a device designed by M Claude which he calls a retour en arrière (reflux apparatus)

Let us imagine that the liquid after separating from the gas encounters a gaseous mass richer in oxygen The liquid is colder on account of the large proportion of nitrogen it contains A part of the more condensable oxygen of the mixture will therefore be liquefied and take the place of nitrogen which will vaporise Thus by circulating in opposite directions a liquid and a gas having different contents there is obtained on one hand a liquid very rich in oxygen and on the other practically pure gaseous nitrogen This process utilizes, moreover a large amount of air which never needs to be liquefied

* Translated from the Smithsonian Institution Annual Report from the Revue Générale des Sciences pures et appliquées Paris twentieth year No 5 March 15th 1909

† For a description of this machine see F Mathias La préparation industrielle de l'air liquide et ses applications les gaz liquéfiés *Revue générale des Sciences* vol xi 1901

‡ Readers desirous of obtaining the details of Claude's processes will find an account of them in the following G Claude Air liquide Oxygène Azote Paris H Dunod and E Pinat 1909

* Duhem: Traité de Mécanique chimique, vol. IV, Chap. 4, Paris, Hermann

M. Claude has utilized this principle of reflux in the following way. A sort of small tubular boiler is arranged so that its axis is vertical. The tubes are surrounded on the outside with liquid air and into the lower ends of these tubes is led a current of cold compressed air. This liquefies progressively, giving liquids poorer and poorer in oxygen; these liquids in falling into a receptacle below encounter gases rich in oxygen and produce the gradual dilution, the principle of which we have described. There finally separates out at the top of the group of tubes practically pure nitrogen, while liquid with a high per centage of oxygen is continually drawn out of the lower part.

A second obstacle remains still to be overcome. Instead of air supercharged with a volumetric content of 47 per cent oxygen, it is necessary to obtain practically pure oxygen. This can be attained thanks to processes of rectification based on those employed in the alcohol industry. In such a process there are two circulating streams inside of a column, one from the bottom to the top of practically pure oxygen gas, and the other from the top to the bottom of liquid containing a large proportion of nitrogen. The latter being colder condenses the oxygen and allows its nitrogen to escape in a gaseous form according to the process which we have seen developed in connection with the reflux apparatus.

The apparatus for this purpose is again composed of a sort of tubular boiler with its axis vertical. At the upper end it continues into a column with condensing shelves such as is used in the alcohol industry. The vertical tubes of the boiler are surrounded by practically pure oxygen and into the interior of these tubes cold air is introduced at a pressure of about five atmospheres. As previously explained this air becomes liquefied, giving in the lower part of the boiler liquid air surcharged with oxygen and in the upper part practically pure gaseous nitrogen. This is carried through the liquefied oxygen and in turn becomes liquefied. The superoxygenated liquid is carried up (through a tube) by its vapor pressure and flows continuously into the central part of the rectification column. The liquid nitrogen is conveyed to the summit of the column. The oxygen vaporized in the tubular chamber on account of the condensation of the air in the interior of the tubes encounters in the rectifying column liquids richer and richer in nitrogen; there falls back in the still consequently liquid oxygen in a practically pure state, while pure nitrogen separates out at the top of the column. The quantity of liquid oxygen which falls back into the still is greater than the amount which vaporizes and ascends into the rectifying column. This excess of oxygen is drawn off and led by way of an economizer to meters and to apparatus where it is used.

Such is the principle of the Claude method for the production of practically pure oxygen and nitrogen. The Linde method differs only in certain of its details. The Bardot factory, which works the Linde process at Aubervilliers, at present produces about 50 cubic meters of oxygen per hour. The Société de l'Air Liquide, which uses the Claude process, has placed in operation apparatus capable of producing 100 cubic meters of oxygen per hour. The yield is about one cubic meter of pure oxygen per each horse power effective on the shaft of the compressor in apparatus of 50 cubic meters and about 1.19 cubic meters for those of 100 cubic meters capacity.

This method of reflux has also made it possible for M. Claude to extract pure gases such as neon and helium from the air. The apparatus enables him to extract as a by-product of the industrial manufacture of oxygen and nitrogen a mixture of nitrogen with at least 50 per cent of neon, helium and hydrogen. To accomplish this the gaseous residues which are strongly resistant to liquefaction are drawn out in the proportion of 6 000 liters per hour for an influx of air of 3 500 cubic meters from the lower parts of a tubular system cooled by liquid nitrogen. By the conjunction of a pressure of four atmospheres and a very low temperature all the liquefiable parts are condensed and the gaseous residue, if the quantity is well regulated, consists of an almost pure mixture of neon and helium.

The liquefaction of air is not the last obstacle which men of science have overcome in the field of gas condensation. Helium, which long resisted the efforts of all physicists, has finally been liquefied by M. Kammerlingh Onnes in the cryogenic laboratory at Leyden* whose installation admits of the attainment of a range of temperatures from 0 deg. down to —253 deg. C. By cooling down helium by hydrogen boiling in a vacuum and suddenly expanding the gas compressed to 100 atmospheres the Dutch scientist has obtained a transparent colorless liquid boiling at —269 deg. C. with a density of 0.154. The critical constants of helium appear to be in the neighborhood of —268 deg. C. and three atmospheres.

Thanks to the admirable scientific equipment of the laboratory at Leyden, M. Jean Becquerel has been able to study at very low temperatures the phenomena of liquid absorption and emission, such as the magneto-optic phenomena in crystals and solidified solutions. This work of Becquerel, so important in its significance, bears on the following points:

(1) Observation of the influence of variations of temperature on the abnormal phenomena of absorption and dispersion. Laws of the variation of the width of bands and the existence for each band of a maximum absorption. Calculation of the number of corpuscles producing absorption. Spectral analysis at low temperatures.

(2) Study in crystals and solutions of a phenomenon of the same nature as the Zeeman effect. Invariability at varying temperatures of period changes produced by magnetism. Observations at low temperatures of phenomena showing the variation in stability of vibrating systems where their period is modified.

(3) Rotary magnetic polarization at low temperatures. Explanation of rotation in the vicinity of the band of absorption. Generalization of the phenomenon of rotary magnetic polarization. Extension of the phenomenon to biaxial crystals. Joinder produced by a magnetic field of two principal vibrations normal to the lines of force. Experimental proof of the existence in a body submitted to a field normal to a luminous ray of a longitudinal component of electric force.

As M. d'Arsonval has so aptly pointed out in his paper at the close of the conference, the study of these phenomena gives new results on the nature, the movements and the number of the electrons which produce absorption. It contributes to the extension of our knowledge as to the ultimate constitution of matter.

The study of the phenomenon of magnetic saturation at low temperatures permits, as M. Pierre Weiss has remarked, of the determination of the magnetic moment of the molecule.* This quantity is fundamental in the expression of the law of corresponding magnetic states, a law analogous to that of the same name which governs the compression and dilation of bodies.

A study of such importance as the molecular modification of bodies is rendered possible by the well known fact that electric conductivity increases as the temperature is lowered. The creation of powerful magnetic fields by simple coils cooled down and traversed by very intense currents permits the realization of the atom and allows it to be transformed and its movements modified.

For this reason the first section of the congress adopted the following resolutions presented by Messrs. Jean Perrin, Mathias and Kammerlingh Onnes:

(a) In view of the extreme importance which is attached to the modification of atoms and the possibility of attaining this result by means of an intense magnetic field (a possibility which the Zeeman phenomenon has already demonstrated) the congress offers the resolution that the nations should unite for the construction of a great electro magnet without iron, the efficiency of which shall be increased by an intense refrigeration.

(b) In view of the admirable scientific equipment of the cryogenic laboratory at Leyden and the hospitable offer of welcome made by Prof. K. Onnes to the investigators of all nations, the physicists present at the first section of the Congress of Refrigeration express the following resolution: That the governments of the nations represented at the congress should furnish necessary assistance to permit physicists to carry out at the cryogenic laboratory at Leyden researches with regard to physical properties at very low temperatures.

"(c) The congress resolves that an international association shall be founded to further such study, scientific or otherwise, an association with its head quarters at Paris, which, while aiding the already specialized fields of research, shall undertake the study of the whole domain of low temperature.

In view of the high degree of interest which attaches to the carrying out and co-ordinating of scientific research in the field of low temperatures, the congress resolves that the bureau of section A shall be charged with the organization of a permanent international association for the study of all scientific questions relating to low temperatures.

II. REFRIGERATING MEDIA.

In the storehouses where at the present day food stuffs are preserved by refrigeration, low temperatures are obtained by the vaporization of the following liquefied gases: Ammonia, sulphurous anhydride, carbon dioxide and methyl chloride.

The liquefaction of these refrigerating agents may be attained (1) by means of a compression pump (compression machines); (2) by means of a solvent such as water (absorption machines). In the compression machines, which are at present the most widely used in the refrigerating industry, the gas liquefied in the condenser or liquefier passes by way of a regulating cock into the refrigerating chamber or evaporator; there it is vaporized by a pump which draws out the vapor, compresses it and sends it to be liquefied again in the condenser. In the absorption machines there is also a liquefier connected with a refrigerating chamber by a stopcock. The compressor —the aspirating and force pump— is replaced (a) partly by an absorber in which the vapors from the refrigerator (in these machines as a matter of fact ammonia gas is used) are dissolved in water; (b) partly by a boiler where the heated ammonia solution gives off ammonia gas. This is again condensed in the liquefier.

The utilizable effect of such a machine or its refrigerating power is measured by the quantity of heat absorbed in the refrigerator during a certain period, or, as is sometimes said, the quantity of cold developed in the refrigerator during the same period.

As M. Barrier has remarked, this power varies widely with the temperature of the refrigerating agent at the condenser and at the refrigerator. The specification of these temperatures affords the only means of comparing with any exactitude the claims of machines made by different constructors and the only means of avoiding difficulties in commercial contracts and exchanges.

Furthermore different countries adopt different units to express this refrigerating power. In France and Germany they express the refrigerating capacity by the number of kilogram calories absorbed or kilogram frigories (negative calories freed) per hour). In England and in the United States they prefer to measure the refrigerating capacity for a day of 24 hours and express it in tons of refrigeration, but in England the refrigeration ton is equal to 81 300 kilogram frigories, while the refrigeration ton in the United States only amount to 72 600 kilogram frigories. Lastly, moreover, in the United States the constructors and consulting engineers often express the cooling capacity of the machines in gallon degrees per minute, the temperature of the refrigerator being kept at 10 deg. F. (—23.3 deg. C.). Such a unit is equal to 110.24 hour frigories.

It would be very useful to adopt for the refrigeration capacity and for the different quantities which have to be considered in the refrigeration industry a perfectly coordinate system of units like that used in electricity.

M. Maurice Leblanc has submitted a very carefully studied out report on this subject. But in view of the opposition of the English speaking delegates, the question does not seem to be fully settled, and Section II has passed the following resolution:

That an international scientific commission composed of theoretical and practical specialists in the subject of low temperatures shall be appointed to consider values, units and notation suitable to the refrigerating industry, and shall report at the next congress. It is to this commission that the proposition of M. Kammerlingh Onnes to give the name of Carnot to the unit of entropy has been referred.

This same commission has been likewise charged with the duty of fixing the temperatures of condenser and refrigerator which shall be adopted so that the refrigeration capacity of a machine may be defined. Section II has only been able to take the following resolution on that subject: That the normal capacity of a refrigerating machine shall be defined by the number of thermal units it can produce in an hour at the given temperatures of the gas at condenser and refrigerator, the choice of these temperatures and thermal units to be left to the determination of the international commission charged with the selection of units.

As a corollary to these resolutions it is likewise desirable to unify the methods of testing refrigerating machines. For this reason the following resolution has also been adopted by Section II: That the question of simple, practical and uniform methods of testing refrigerating machines, based on the units defined by the international commission and applicable to the different types of machines and to different circumstances of installation, shall be made a subject of study with a view to international agreement.

(To be continued.)

From the *Mineral Survey of Ceylon*, the initial stage of which may now be regarded as practically completed, it is clear that the island contains, in addition to gem stones, a number of minerals of commercial importance, of which only graphite, mica and thorianite are at present worked. The mining of graphite is on a large scale and in some cases is under European supervision. This mineral is an important article of export. Mica is only mined to a small extent by primitive methods, but there is room for further enterprise in this material now that it is known that much of the Ceylon mica is of value for special purposes. Thorianite is a new mineral discovered as a result of the operations of the survey. Comparatively large quantities have been profitably exported in recent years and utilized in this country as a source of the thoria used in the manufacture of the incandescent gas mantle.

Modern Deluge Sets for Fire Extinguishing Service

Heavy Streams and How They Are Handled

By Frank C Perkins

It is the criticism of many fire experts that in the past altogether too little attention has been given to the water stream either as regards character body or manipulation The chief thought has been to shorten the time required to reach the fire which has been cut down from minutes to seconds by the introduction of modern improvements It can not be denied that in this respect progress has been along the right lines

But this much being accomplished the next step should be the adoption of a system of producing and handling streams which would with equal promptness stop the fire Our illustrations show a number of devices designed especially with this object in view and aiming to produce a stream of great compactness and carrying power

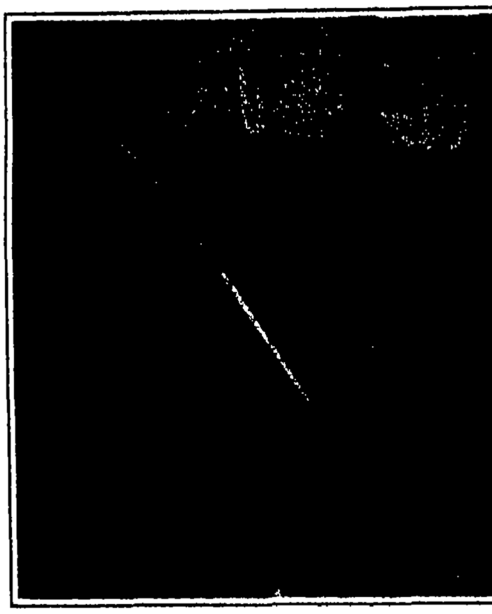
It is well understood that the stream of water in order to be effective must be increased in size and distance as nearly as possible in proportion to the extent of fire since heavy streams only are effective on large fires Many people are not aware that such heavy streams can be produced from ordinary pressures by the employment of proper nozzles for the purpose

Almost every fire department is equipped with chemical extinguishers and nozzles giving ordinary sizes of streams such as are indispensable for ordinary fires but in many cases they are not equipped for coping with the greater disasters caused by fire While ordinary fires have been provided for exigencies of great conflagrations to which are due the heaviest losses in this country have not been met

With the latest nozzle system for producing and handling powerful streams it is possible for every fire company to have at hand at a very small expense all sizes of streams whereby immediately to meet any conflagration with a stream of water in proportion to the size of the fire

These modern deluge sets are very light and compact and can be put in operation at a moments notice the 3½ inch reducers being provided with the same thread as the regulation 2½ inch hose thread in the department so that upon reaching a fire the deluge set can be placed upon the line of hose at any point desired the ordinary 2½ inch line of hose for inside work can then be extended to any place desired by simply turning off the deluge nozzle tip If the firemen are driven out of the building the 2½ inch line of hose can be disconnected from the deluge line the nozzle tip replaced and the deluge stream with all its force then projected into the fire without loss of time With these modern deluge nozzles any section of the 2½ inch hose in the fire department can be adapted to deliver as large streams as may be profitably used on 2½ inch hose.

A special holder is provided for handling these heavy streams taking all the weight and reaction from the man at the nozzle so that he is able to direct the stream without difficulty under pressures which



TWO INCH STREAM FROM 150 POUND HIGH PRESSURE SERVICE

without these devices would require several strong men to control

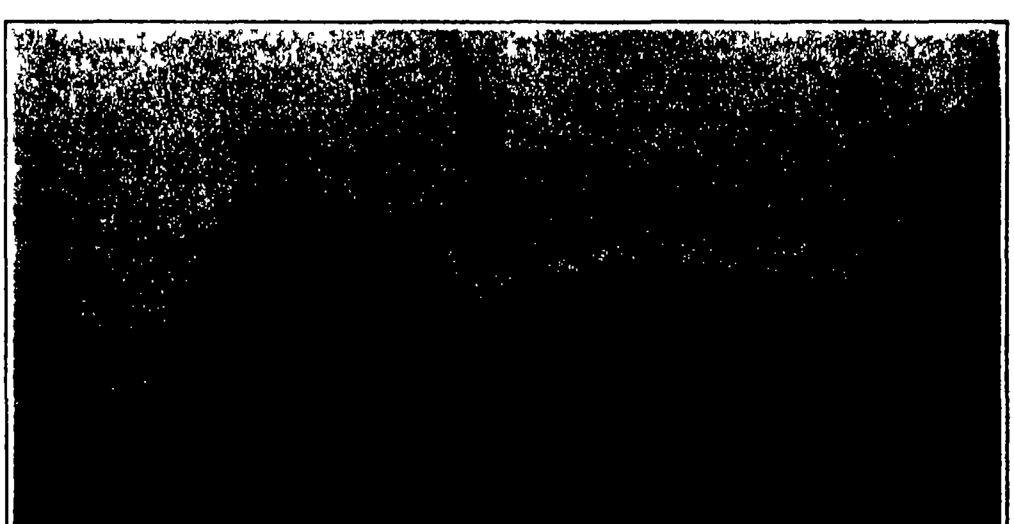
It will be readily seen that when firemen have at their command the means of adjusting the stream to the conditions of the fire a principle will have been adopted which will more than double the efficiency of the fire service and which will reduce fire losses and insurance rates by the millions In fact this change has already in part taken place

There has been devised a special reducer which turns directly on the male coupling of any section of hose The construction of this reducer is such that it takes all twist and whirl from the stream and brings water friction to a minimum The water leaves the nozzle in a straight solid stream which carries nearly all the water undivided to the end A stream without solidity is deficient in carrying power and almost worthless against a strong wind

Our accompanying full page illustration shows a 1¾ inch solid stream issuing from the improved type of nozzle in use at Manchester, New Hampshire. In the small view is seen a 2-inch stream thrown from a high pressure service of 150 pounds, the nozzle being supported upon a simple holder and platform, while two of these devices are shown in service in our last engraving one nozzle throwing a 2½ inch solid stream from a gravity hydrant at a pressure of 85 pounds to a distance of 337 feet while the other nozzle is throwing a 1½ inch stream from the same hydrant

The efficacy of the hose-holder has been amply proved It is quite possible for a small child to direct and control the stream from a hose equipped with this holder though the jet of water issuing therefrom be so powerful as under ordinary conditions to severely tax the strength of an able-bodied man

By such careful attention to nozzle design and the details of hose equipment it should be possible to do a great deal to advance the present practice of fire fighting and to save the community much of that loss which is caused annually by the destroying flame



ONE OF THESE NOZZLES IS THROWING A 2½ INCH STREAM TO A DISTANCE OF 337 FEET THE OTHER IS A 1½ INCH NOZZLE BOTH ARE ON AN 85-POUND HYDRANT

MODERN DELUGE SETS FOR FIRE EXTINGUISHING SERVICE

The Function of Soap in Insecticides

Some iteresting researches upon insecticides are reported upon by Messrs Vermorel and Dantony of Paris There are two general classes of insecticides, those which act as poisons on the food of the insect and others of the external kind which kill the insect by simple contact. It is the latter which are considered by these authors One of the essential points to be borne in mind in the making up of such preparations is the necessity of providing for an intimate contact with the insect In order to wet a given body in the best way a liquid must be chosen which has a low surface tension However the authors show that with oleate of soda (soap) the same wetting effect is produced by the addition of 5 per cent to the solution as of 0 1 per cent The soap need not be used nearly as strong as is commonly supposed Solutions of 1 in 1 000 are as efficient as those of 50 per 1 000 For hard water a little carbonate of soda should be added A very cheap mixture is to use with flowers of sulphur one per cent of soap and the same amount of carbonate of soda and we have a product which wets instantly Thus with the usual dose (20 pounds sulphur per 100 gallons of water) the solution needs to contain but 2 in 10 000 of soap They find that alcohol is not needed here to increase the moistening action. The major part of coleopters and grape vine insects are instantly wet with 5 per 10 000 soap solution Insect webs are moistened by 1 in 1,000 solution

Mirage in the Metropolis

The London *Times* publishes a letter from Mr H Thompson Lyon describing the occurrence in the heart of London of an optical phenomenon that one associates with burning deserts and barren plains, rather than with the streets of a great metropolis Mr Lyon writes

"I witnessed this afternoon at a quarter to 3 o clock a remarkable example of the mirage on the north side of Grosvenor Square The whole surface of the roadway appeared a sheet of water My first impression, before I realized what the phenomenon was, was that a water main had burst and flooded the road On approaching closer the water broke up into pools and then disappeared altogether There was no one about except the policeman on duty and he would not believe me until he had gone up to the spot, that the road was perfectly dry He called my attention to the disturbance of the heated layer of air by the motor cars which exactly reproduced the effect of wheels splashing through shallow water I have frequently seen the mirage in the desert of the Sudan, but I have never observed a more realistic exhibition It would be interesting to learn if other instances of mirage have been observed in this country"

In reply to the query at the end of this letter, the Quarterly Journal of the Royal Meteorological Society states that a mirage was observed in London by Dr Wollaston, F R.S., in 1797

In attempts at reforestation of the treeless areas of our national forests by the Forest Service it was found that on an average half of the seed was dug up and eaten or carried away by mice and chipmunks. Attempts to poison the animals, however, have proven very successful Oatmeal mixed with strychnine and water, or wheat coated with hot tallow mixed with strychnine as a protection against rain or moisture, proved very effective. The poison should be distributed several days in advance of the seeding.

A Remarkable High Power Electric Locomotive

A 1000-Horsepower Plant on Wheels

OUR illustrations present views of a very interesting electric locomotive in operation on the Wiesenthal bahn in Baden. The weight of the locomotive is 66½ tons, it measures 43½ feet in length and 10 feet in width The adhesion weight is 42 tons There are six driving wheels of 4 feet diameter coupled to the elec tric motors by connecting rods with 20-inch stroke The smaller wheels at the leading and trailing end are 2 1/3 feet in diameter and the total wheel base is about 30 feet the fixed base of the drivers being 11½ feet.

The locomotive carries two 500 horse-power motors giving a total output of 1,000 horse-power on normal load with a maximum draw bar pull of somewhat over 10 tons. It makes 42 miles an hour hauling a train of 12 passenger coaches with a seating capacity of 51 each (aggregate weight 230 tons) or 27 to 30 miles an hour taking 15 to 20 freight cars (500 tons) The motors are of the multipolar type and are capable of giving 800 horse-power each in an emergency

The power is supplied by the Rheinische Kraft werke in August at 10 000 volts and 15 alternations per second. The locomotive was built by the firm J A Maffei of Munich and is giving full satisfaction One of the heaviest grades on the line between Basel and Zell figures about 1 100 and is negotiated without the slightest difficulty

Are Time and Space Infinite?

THE question proposed above forms the subject of a discussion which has appeared in *Popular Astronomy* in particular the affirmative answer is ably sus tained by C H Ames from whose plea we quote some of the most striking passages

'Every one recognizes that a finite space implies or presupposes larger space to exist in So on reflec tion just as truly does its environment As we pass from one space to another we are still in space and all finite spaces are parts of space itself— the all comprehensive and necessary reality which makes finite spaces possible

Hence space is limited only by space i e self limited i e universally extended and infinite There is and always must be space" beyond any and all spaces and when we say always must be we have the true undeniable and perfectly satisfac tory thought of the infinite Why do we unhesitat ingly say and always must be? This brings us to the most important distinction which it is possible for the mind to make and the one which when clearly perceived will solve a vast number of knotty prob lems and prove an emancipation of the mind from the unwelcome tyranny of one of our faculties which yet seems to so many persons to be unescapable

It is true that most of the thinking of mankind is what might be called image thinking It may even be admitted that most of it must be of this kind and not only accompanied by but in a sense dependent on the image the mind makes of imagable things

The question is whether there is another kind of thinking and a superior kind which whether *accompanied* or not by images is not in any sense *dependent* on them for its cogency and reliability It is certain that there is, and that even the ordinary and perhaps not very reflective man makes not infrequent use of it, as, for example when he says of a repeat ing decimal "and *so on forever* We say that two and two are four We hold the terms of this state ment clearly in mind and cannot frame a doubt of its certitude But we quite as confidently affirm that two quintillions and two quintillions are four quintillions What are the grounds of our certitude in the second case? We realize that it is our insight into the na

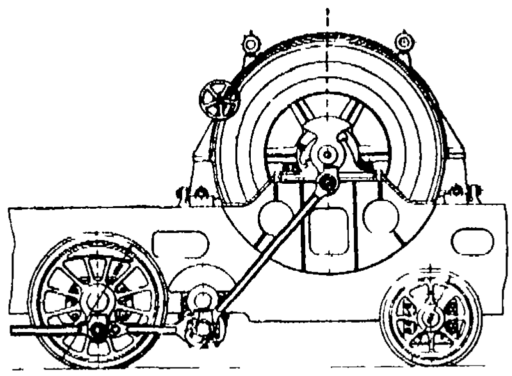


FIG 2—DETAIL VIEW SHOWING COUPLING OF MOTOR TO DRIVE WHEELS

ture of the case In other words it is our direct in sight into reason on which we rely and not at all on our power to envisage or imagine the separate units of this stupendous sum

Moreover we know that the truth we have so positively stated not only is true now but we are equally sure that it always was and always will be true and that we have here a regal and transcendent power of the mind of a wholly different order from that which depends on the power to create images which in order to *be* images *must* have borders and limits and must from their very nature be finite

Thus we may know thoroughly the *nature* of not *only* the finite but *also* the infinite *It is the power* of reason as contrasted with that of imagination The mind then is capable by the insight of reason of knowing that which the imagination from the na ture of the case is utterly powerless to cope with It sees the infinite is never the indefinite but the *self* limited and that this is a positive and satis factory result The indefinite is never the infinite though almost universally it obtrudes itself when the infinite is spoken of The indefinite is when seen correctly the *not yet defined* but that which for all that we know may yet sometime be defined,

But the true infinite of which we may have any number of examples and of which we may make constant and most important use is never of that kind Bearing its definition and nature constantly and unswervingly in mind we may affirm with ut most confidence and positiveness that both space and time are *truly* infinite

The mental protest which the imagination instantly makes is *only* the protest of the imagination which not only *may* be but *must* be set aside as impertinent and meaningless in the light of our higher insight

The effort of the imagination to find an end to space or a beginning to time may be seen from the outset to be futile In such effort the imagination as Herbert Spencer truly says sinks exhausted as we know it was doomed to do and its effort is not sublime but merely tedious and foolish and in no wise throws doubt upon the deliverance of reason or presents any dilemma in regard to it

If one should ask the shape of space whether spherical or otherwise his question dissolves in ab surdity when he realizes that he is thinking of space not as infinite as we know it must be but as finite a space requiring larger space of the old fashioned sort, to exist in and hence he is a victim of his imagination and can be emancipated from this ty ranny only by reliance on his reason What is true *of space in this regard is equally true of time* as will be readily seen Space and time then are truly and positively infinite despite the protest of the imagination

In the light of this thought the difficulty found with the thought of time and space disappears

Professor Pickering has said If it is difficult for us to imagine infinite space it is still more so to com prehend infinite time As we go back eternally through the ages how is it possible for there to be still an infinity of time before that? Yet we cannot conceive of an actual day or instant before which time did not exist

We see that in these few lines Pickering has used the terms imagine comprehend and conceive as interchangeable and without difference of meaning It is therefore not surprising that he is led into men tal tangles in which he has recourse to such gro tesque and as Herbert Spencer says only verbally intelligible expressions as those relating to time and space so curved that they return into themselves

It is the contention of this article that the trouble with the notion of infinite space is but the protest of the imagination and therefore negligible and that therefore the recourse to notions of a curved space and even a curved time of such nature that if we could go back far enough into yesterday we shall arrive at to morrow is as needless as it is fantastic and absurd

* Dr August Schmauss has been appointed director of the official meteorological service of Bavaria suc ceeding the late Fritz Erk

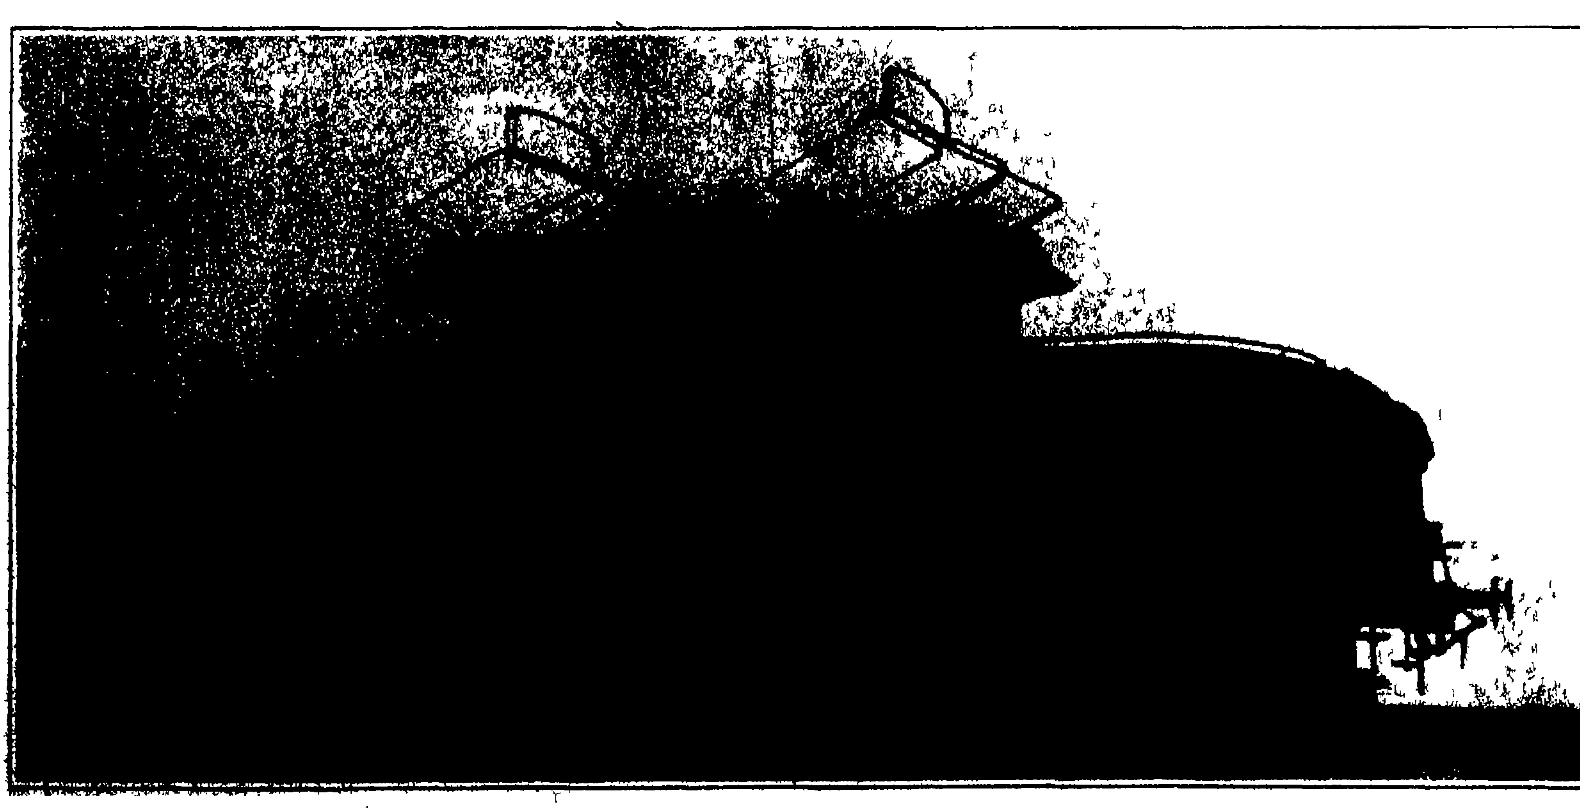

FIG. 1—A NEW ELECTRIC LOCOMOTIVE ON THE WIESENTHALBAHN BADEN

The American Navy*

Its Material and Its Personnel

By George von Lengerke Meyer, Secretary of the Navy

It is not perhaps generally known that Lincoln's military activity during the Civil War included naval operations as well as military operations on land. His orders and instructions to commanders of joint expeditions required the most perfect co-operation. He did more than merely approve plans submitted to him; he originated many of them. His mind readily solved most of the war problems submitted to him though the men and means were not always available for success.

Lincoln had the greatest confidence in the integrity of Hon. Gideon Welles, his Secretary of the Navy, and in the efficiency and ability of Captain Gustavus Vasa Fox, the Assistant Secretary of the Navy. Through the latter he maintained close relations with all naval operations.

Throughout the war Lincoln's custom was to spend a portion of every evening with Captain Fox in the telegraph office at the Navy Department and through his relations with him and the Secretary of the Navy he was in close touch with practically every detail of naval operations of the Civil War, including all independent and co-operative movements, and he clearly defined the relations between the naval and military services as strictly co-operative rather than subordinating one to another.

Lincoln is quoted as saying: "The Mississippi is the backbone of the Rebellion. It is the key to the whole situation. While the Confederates hold it they can obtain supplies of all kinds, and it is a barrier against our forces."

Lincoln's personal interest in Farragut's campaign was so great that when the Admiral hesitated about ascending with his ocean-going vessels from New Orleans to Vicksburg, Lincoln sent him through the Navy Department imperative orders to proceed up the Mississippi to meet the fleet of the Mississippi River Flotilla from above.

His admirable judgment is evident in all his orders regarding naval affairs during his entire administration. While entirely ignorant of technical and tactical details, his power of logically arranging groups of facts gave him a clear insight, and better still, real foresight in all larger strategical questions.

In Lincoln's time the largest ship was the Niagara, a screw vessel of 6,000 tons. Her complement was 30 officers and 400 men. No gun of the type used on vessels from 1861 to 1865 fired a projectile that could penetrate the armor of the modern battleship.

The Monitor, completed in 1862, was the first step toward the modern dreadnought. The first dreadnought, launched in 1906, has a displacement of about 18,000 tons and a battery of ten 12-inch 45-caliber rifles. The battery of the Monitor consisted of two eleven-inch smooth-bore guns firing projectiles weighing 170 pounds. She had a displacement of about 1,000 tons and a draft of 12 feet. Though smaller than the Merrimack, she was of superior strength on account of her heavier guns and armored turrets. The Merrimack was of 4,600 tons displacement, covered with iron plate like a box, and had ten guns, including six nine-inch guns.

THE DREADNOUGHT TYPE CONCEIVED IN AMERICA.

It is not generally known that in the summer of 1903 the ideas of the all-big-gun ship was conceived in the American Navy, and a sketch was submitted for the consideration of the officers in attendance at our War College in Newport, R. I. This plan was discussed at the War College during that summer. In January, 1904, the General Board, having considered the suggested plans, requested the Department to direct the Bureau of Construction and Repair to prepare tentative designs for a battleship with a battery of twelve heavy turret guns. The letter was referred to this Bureau by the Secretary of the Navy with directions to prepare such design. In September of the same year the General Board asked to be informed by the Bureau of Construction and Repair how soon the tentative design would be completed, but the Bureau had been preparing plans for the South Carolina and Michigan on lines similar to those of the Connecticut with a mixed battery. Finally, in September, 1905, it proposed the all-big-gun design for these ships. In the meantime, however, England had been at work on the British battleship Dreadnought, the first of her type, which was launched in February, 1906. Had the worth of the suggestion for the Dreadnought type been appreciated, regardless of the fact that the idea originated outside of the design bureau, the United States would have had the honor not only of producing the Monitor, but also the first Dreadnought.

To give an idea of the strength of the modern Dreadnought, I will quote from an article by Professor Hollis of Harvard, printed in the February number of the *New York Engineering Magazine*. He says: "A single one of the American battle fleet lately returned from Europe, in the hands of the Confederacy would have destroyed the entire Northern Navy. Not a ship, or any combination of the ships then existing, could have remained on the blockade. The cost of a modern ship must therefore be contrasted with that of our entire navy in the past of only forty years ago, in order to get anything like a fair idea of what should be paid for new ships."

The enlisted force of the Navy in 1864 was about the same as it is to-day, while the number of vessels in commission was 683, with a displacement of 500,000 tons, as against 212 vessels in commission in 1910, with a displacement of 790,000 tons.

THE NAVY BEFORE AND AFTER THE CIVIL WAR.

The Navy to-day differs from that of twenty years ago not only in ships and guns but in men. Few people appreciate the fact that 96 per cent of the enlisted men to-day are American born, representing every State in the Union. They have not been seafaring men, but are young men of high intelligence from every walk in life. As soon as they are enlisted they are sent to a training station, where they are taught sanitary care, drilled in the necessary exercises pursuant to their vocation, and within three months are generally placed on a battleship or other man-of-war. Here they are developed according to their inclinations and ability in electricity, machinery, gun firing, and all requirements of a modern man-of-war to such an extent that when their enlistments expire they are a valuable asset to the country. The Navy increases their productive powers for times of peace and makes them a strong instrument for defense in time of war.

The duties of the officers have also changed materially. The battleship fleet, which is the navy, and to which the country would look in time of trouble, is composed of enormous ships which are floating power plants full of complex machinery. Consequently it is necessary that the officers should be versed in engineering as well as seamanship. Roosevelt once said every officer must be a fighting engineer. To command, or to be the executive officer of one of these great moving machine shops requires technical knowledge, executive ability, mental training, and a physical condition as nearly perfect as possible in order to be able to stand the strain and responsibility.

One of the most far-reaching acts of our former President, Theodore Roosevelt, was to issue an order directing our battleship fleet of sixteen vessels to encircle the globe. At the time the success of this movement was considered by many but not by him as problematical and hazardous. No such armada had ever attempted a similar voyage, and there were many critics at home and abroad who were skeptical and opposed to it. However, it was a stupendous success, with far-reaching results. It served as a messenger of peace instead of a menace to the world. It was received with enthusiasm and cordiality everywhere. It impressed the world with the power and skillful handling of the American Navy. The American people were proud of their ships and men, and pleased with the entire success of the cruise.

NAVY ORGANIZATION.

When I became Secretary of the Navy I found an organization dating back to the year 1842, when the expenditures were about eight and one-quarter millions of dollars and the number of sailors and marines were about eleven thousand. In 1842 but 29 vessels were in commission, with a tonnage of 30,000 tons.

In 1910 we expended approximately $135,000,000 for the Navy, had 57,000 sailors and marines, 212 vessels in commission, and a tonnage of nearly 800,000 tons.

I made it a point to study the reports of former secretaries of the Navy, of Boards of successful shop and shipbuilding organizations, and the great navies of other countries, and finally adopted in part the recommendations of a commission which had been appointed by Mr. Roosevelt. This commission was presided over by Justice Moody and included Admiral Mahan, Judge Dayton, the late Paul Morton, Rear Admiral Luce and Rear Admiral Folger. It was the report of this commission which the Swift Board appointed by me used as a basis for the reorganization which is in effect in the Navy Department at the present time. This organization is logical and successful, and the responsibility is now on Congress to make it statutory.

While I was before the Naval Committee recently arguing for two of the latest Dreadnoughts, it was suggested to me by one member that, as battleships' hulls with their steel construction did not become unseaworthy, instead of building a 30,000-ton battleship, we might reconstruct three of our 15,000-ton battleships to take the place of the one proposed. This member did not appreciate the fact that if the same old guns were kept on the smaller ships, the larger vessel with more modern guns and better armor and more speed could choose her own distance and annihilate the smaller vessels. But even if the reconstructed vessels had the best guns and the same speed as the large modern battleship, the three together could not be maneuvered with the facility that the one large one could. Thus the one large vessel could concentrate its enormous gun fire on the smaller vessels in turn and destroy them in detail.

To reconstruct and bring up to date is a costly and unprofitable undertaking. No one would think of reconstructing a locomotive or a street car after many years of service—then why a battleship, when the result is so poor.

The fleet, if kept up to date and with the proper military efficiency, is an insurance against war. As long as our fleet is efficient and of sufficient size we can be sure that we will not have war.

The object of the present organization in our Navy is to maintain the highest military efficiency, that is, a preparedness for war on the part of the fleet.

I have aimed to establish up-to-date business methods in the Department and navy yards. The result should be economy throughout the entire naval service, with the assurance that whenever a dollar is expended full value will be received.

In order to keep track of what is expended, a new system of bookkeeping has been established by which trial balances can be furnished monthly. This has not been possible heretofore. Cost accounting has been systematized so that hereafter comparisons can be made between the various yards. Stores have been consolidated from seven store accounts into one property account. The Naval Supply Fund is to be abolished and $2,700,000 is to be turned back into the Treasury for general use of the Government.

In navy yards there has been a logical division of work into the divisions of hull and machinery, a system adopted in our successful private shipbuilding plants as well as in the English and German navies. The abolition of the Bureau of Equipment has been recommended, its duties to be divided logically among the other bureaus. Congress has, however, neglected to do this as yet.

HOW THE NAVY DEPARTMENT CONDUCTS ITS BUSINESS.

The business of the Department has been grouped into four natural divisions, and assigned to each division is an experienced officer, who acts as an aid to the Secretary of the Navy. These aids keep him informed and serve as his expert and responsible advisors. They are the Aid for Operations of the Fleet, who attends to matters never before provided for systematically; the Aid for Inspections, who carries on a systematic and thorough inspection ashore and afloat, with the object of avoiding large expenditures on vessels which would not be a military asset after the money had been expended; the Aid for Personnel, and the Aid for Material, the last covering the material bureaus. With this organization, and the hopefulness inspired by the motto now adopted, that "The Fleet is the Navy—the Navy is the Fleet," we find to-day a healthy spirit of co-ordination in the navy and a zealous aim to get efficiency as well as economy.

Competitions have been introduced in the fleet not only in gun practice but also in the consumption of coal and the use of stores. This has resulted in a saving in expenditures and in even higher efficiency.

To give a brief idea of the improved administration of the fleet and the navy yards, the following is interesting:

The Paymaster General of the Navy, on comparing the cost of administration of the navy yards for 1910 and 1909, finds that if the gross charges had borne the same ratio to the productive work in 1910 as in 1909, the gross charges would have been proportionately greater by $3,166,307.

In 1909 there were 196 vessels in commission, and in 1910 there were 212. If the cost of maintenance per ship had been as much in 1910 as it was in 1909, the expenditures afloat, it is calculated, would have been increased $4,113,331.

The gain in administrative economy and operative efficiency of the navy may be indicated by adding these sums together, showing that but for better business

* Abstracted from an address at the Lincoln Day dinner of the Republican Club of the City of New York, Monday evening, Feb. 13th, 1911.

methods, $7,278 628 more would have been spent, in other words, the operating expenses of the navy have been reduced by that amount.

During the year in which this improvement has taken place the number of ships increased about 8 per cent the average number of ships actually in commission was increased about 11 per cent and the displacement of vessels was increased about 9 per cent

The power of motive machinery was increased about 16 per cent, and the average cruising speed of the fleet has increased from 10 to 12 knots without additional consumption of coal.

Thus greater efficiency has resulted with more economical administration

The indicated improvement in economical administration amounts to about 9 per cent of the total amounts expended for running the navy yards and ships or 6 per cent of the total expenditures for the entire year for all purposes

CONDUCTING THE NAVY ON A WAR BASIS

Ships are now moved in squadrons or fleets engaged in battle practice maneuvering and gun firing Everything is carried on as though war existed or might exist at any moment The principle being that to be prepared for war is to avert war

Our ships are giving strict attention to self maintenance and to keeping of vessels in repair by the enlisted men They only go to the navy yards for docking and for large repairs

In all these reforms and recommendations I have had the entire endorsement and hearty support of President Taft without whose aid and sympathy little could have been accomplished He also is very desirous and keen that we should build two battleships a year

With the opening of the Panama Canal the importance of the Caribbean Sea as a base of future naval operations will be realized It is the hope of the Department to have a naval base in the accessible and suitable harbor of Guantanamo Cuba which is some 700 miles from the canal and capable of harboring a fleet of fifty or more men-of war

It is important during battle maneuvers in peace or a period of real hostilities that a vessel should not be called upon to return two thousand miles in order to be repaired This can more easily and economically be done by the development of Guantanamo as a docking and repair station I have recommended to Congress that certain useless naval bases and yards should be abolished, bringing about a saving of about a million and a half dollars annually in maintenance for these yards alone Congress must assume the responsibility if this is not accomplished as it requires legislative action

It is the intention to develop Pearl Harbor San Francisco Bay and Puget Sound in order that after the Panama Canal has been completed the entire fleet may be maintained on the Pacific Coast

PRIVATE YARDS VS GOVERNMENT YARDS

At the present time Congress is in the midst of a discussion as to the method under which ships should be built—whether they should be confined to an eight hour limitation of labor not only in the Government yards where eight hour labor is the rule now but also in private yards It is interesting to note the extra cost involved and what a detriment it would be to the resources of the country if the private yards are to be driven to an eight hour basis just at the moment when our shipyards are successfully competing with the shipbuilding organizations of the great maritime nations We know that if the vessels of the building program recommended by the President were to be built in the Government navy yards it would cost about $20 775 000 whereas if built under present conditions of labor in the private shipyards without restrictions by an eight hour law there would be a saving of about five and one-quarter millions of dollars The battleship Arkansas which was launched last month at Camden N J was constructed and launched at a cost of four and one half millions or one and one half millions less than the limit of cost fixed by Congress The Florida building at the New York Navy Yard will cost $6 400 000 and its cost will exceed that of her sister ship the Utah (building at a private yard in Camden N J and launched six months ago) by $2 450 000

In the case of the new Texas a thousand tons larger than the Arkansas with the eight hour provision the Department was obliged to accept the one offer of $5 830 000 an advance in price over that for the Arkansas of $1 750 000 although the size had only increased a thousand tons It is estimated that the sister ship of the new Texas (to be called the New York) which Congress provided should be built in a navy yard (which means the New York yard), can not be built for less than $7 500 000 In other words if Congress will permit the New York to be built at a private ship yard a saving can be effected based on the estimate for the Texas even with the eight hour limit of labor of $1 650 000

WHAT THE NAVY MEANS TO THE NATION

The building of the American navy has brought about many advantageous results to the country Before the era of the white fleet (1887) a steel ship had not been built in this country The requirements of the Navy and the studies and aid of naval officers brought about the establishment of some of the great steel plants which are on such a basis to-day that they are able to compete successfully with the world The new Navy is responsible for the education development and training of a large class of men who enter our industrial world It has enabled a number of shipyards to exist which could not have continued but for the Navy These yards are invaluable assets to our country and are prepared when Congress sees fit to encourage our shipping to build the required merchant marine for the United States which will be a valuable adjunct to our Navy

All of us are anxious for universal peace and there are many who feel that it can eventually be brought about by an international supreme court We must bear in mind however that no court can be of any service unless its decrees can be enforced When the nations agree to an international court it is certain that five or six great nations will be obliged to maintain navies in order that the decrees of the court will be maintained It will be necessary that no one of these nations shall have a greater or more powerful navy than the combined navies of the other nation members of the court We may therefore feel sure that the American navy in the future under the most favorable conditions as to peace will have to exist It will have to be ready to do its share in the enforcement of the decrees of this court if established when necessary

With the certainty of an expanding commerce in the future with our surplus products carried to the world's markets and with our growing responsibilities in the region of the Panama Canal a strong navy will be a necessity

The Products of the Soap-nut Tree

By O W WILLCOX and M I RENTSCHLER

ATTENTION has recently been drawn to the Soap Nut the fruit of a tree indigenous in India and Algiers but recently introduced into Florida as a source of Saponine Extracts This is a substance applied to various uses e g as an addition to toilet soaps and other toilet preparations and as a foam producing material in carbonated beverages It is said to be also used by chemical laundries and cloth fullers instead of soap The material at present in most general use in this country for manufacturing saponine extracts is Panama bark (quillaya) Through the courtesy of Mr Moulie through whose efforts some 500 000 young soap nut trees have been planted in the United States we were enabled to secure a couple of pounds of the soap nuts produced by the only tree in America which has reached full maturity and through the courtesy of Schutz & Co of Hamburg we received two kilograms of soap nuts of which this firm is a large importer its supplies being drawn from India and Algiers

In preparing the extract we boiled 50 grams of the chopped hulls with three successive portions of water The three portions were united and then concentrated to about one third of the original bulk The solution was then cooled to below 40 deg C A small amount of egg albumen suspended in water was added the boiling resumed for a few minutes and the solution then filtered hot The addition of the egg albumen was for the purpose of clarifying the solution as otherwise the filtration is exceedingly difficult At first we clarified the solution by addition of Fuller's earth but we find the clarification by egg albumen to be a more satisfactory method We found the yield to be 73 per cent of soluble extractive matter confirming a previous publication of E Walter After the extract has been concentrated to a syrupy consistency it may be treated with fifteen per cent by weight of alcohol the result being a dark liquid essence of high foam producing power The extract so prepared gradually deposits a flocculent precipitate It is advisable after preparing the extract to allow it to stand undisturbed for several weeks until no more precipitate is deposited and then filter it The extract thus finally obtained is a brilliant liquid which does not cause turbidity when added to beverages that are to be carbonated If desired the soap-nut extract may be evaporated to dryness, whereby it is obtained as a light, fawn-colored powder which dissolves easily in water

Through the courtesy of Mr. Hills, president of the Marrowfood Co New York we were put in possession of two pounds of Panama bark We made an extract therefrom in the following manner

Fifty grams of the powdered bark was placed in each of four Erlenmeyer flasks To the first flask was added 250 cubic centimeters of water which was boiled for twenty minutes The extract from this flask was poured into flask No 2 and the boiling repeated Flask No 1 then received 250 cubic centimeters fresh water boiled and the resulting extract transferred to flask No 2 and so on the extract of one flask being transferred to the flask ahead its place being taken by the weaker extract from the flask behind the whole operation partaking somewhat of the nature of diffusion as practiced in beet sugar factories In this way the 200 grams of bark were extracted with the minimum amount of water It is said that some makers of Panama bark extract use 300 gallons of water to get 7 gallons of finished extract which represents a great waste of time and steam in concentrating The yield of dry extract from the bark was 19 5 per cent The yield of the bark is therefore to the yield of the soap nut as 1 is to 3 8 which is quite a difference in favor of the soap nut

We next made some experiments to determine the relative efficiency of the two extracts as foam producers We found that the minimum amount of each required to produce a preceptible foam in distilled water was one part in a hundred thousand To produce a sufficient amount of foam for carbonated beverages however it was necessary to use four parts in a hundred thousand or 0 00025 per cent which is an insignificant quantity

To compare the character of the foam yielded by the two saponine producing materials water was placed in two stoppered cylinders of the same size the same amount of extract added to each then the two flasks were shaken It was found that in comparison with the soap nut extract the Panama bark extract gives a much coarser foam that is one with much larger bubbles The soap-nut foam is in fact very compact and fine grained much more attractive in appearance than the foam produced by the Panama bark extract Moreover although both kinds of foam are very durable the soap nut foam lasts much the longer However this is not a very important point since either will last long enough for all practical purposes

We also made some attempts to determine the relative emulsifying powers of the two extracts when compared with each other and with an equal weight of dry castile soap powder In this test 1 gram of the substance was dissolved in 100 cubic centimeters of distilled water the solution poured into a tall cylinder with a glass stopper 0 2 gram of various powders such as ferric hydroxide and barium sulphate was added the cylinder vigorously shaken and allowed to stand It was noted that the substance settled at practically the same rate in all three cylinders which would indicate that the soap-nut extracts have about the same emulsifying power as soap solution We did not however follow this line of experimentation sufficiently far to warrant definite conclusions

It is interesting to note that the hulls of the soap nut are not the only product of possible value of the soap nut tree The nuts have a hard black seed which is slightly smaller than a hazel nut The shell of the nut is very hard and weighs considerably more than the kernel If ever the soap nut become a commercially important product in Florida the seeds being necessarily a by product they will have more or less value as a source of oil We give below an analysis of the soap nut seed made by us and for comparison the corresponding figures for peanuts to which in respect of its general composition the soap nut seed bears a close resemblance although the flavor and other properties are very different

	Soap Nut Seeds	Peanuts
Moisture	8 40	[illegible]2
Ash	4 04	2 0
Oil	37 18	38 0
Protein	25 38	25 8
Crude Fiber	1 84	[illegible]
Carbohydrates	23 16	24 4

The soap nut seed ash is rich in potash and contains 32 31 per cent phosphoric acid The carbohydrates are chiefly starch pentosans and sucrose No reducing sugar was found Tannin is absent The usual reaction with guiacol and hydrogen peroxide seems to indicate the presence of considerable quantities of peroxidase There is however no saccharifying enzyme present The oil which was obtained by extraction has a bland and very agreeable taste The seed contains one per cent of lecithin

Soap nut hulls of good quality can be bought in Hamburg at 7½ cents a pound which is about the price of Panama bark As however the yield of the soap nut hulls is nearly four times as great as that of the bark the hulls if obtainable in sufficient quantity should have no trouble in driving the bark out of the market

It may be here remarked that many dispensers of carbonated beverages do not use soap nut extract to produce foam —*Pure Products*

Making Money Out of Bees—I*

Keeping Bees for Pleasure and Profit

By E F Phillips, Ph D, in charge of Bee Culture, Bureau of Entomology

INTRODUCTION

Bee keeping for pleasure and profit is carried on by many thousands of people in all parts of the United States As a rule it is not the sole occupation There are however many places where an experienced bee keeper can make a good living by devoting his entire time and attention to this line of work It should be emphasized that it is unwise for the average individual to undertake extensive bee keeping without considerable previous experience on a small scale since there are so many minor details which go to make up success in the work These must be thoroughly understood before there is any hope for continued success It is therefore most desirable to begin on a small scale make the bees pay for themselves and for all additional apparatus as well as some profit and gradually to increase as far as the local conditions or the desires of the individual permit.

Fig 1 —A Well Arranged Apiary

Bee culture is the means of obtaining for human use a natural product which is abundant in almost all parts of the country and which would be lost to us were it not for the honey bee The annual production of honey and wax in the United States makes apiculture a profitable minor industry of the country From its very nature it can never become one of the leading agricultural pursuits but that there is abundant opportunity for its growth can not be doubted

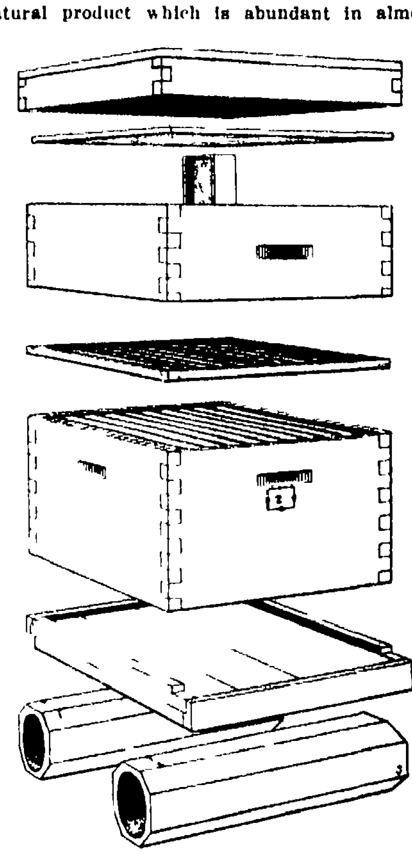

Fig 2 - A Ten frame Hive with Comb honey Super and Perforated Zinc Queen Excluder

Not only is the honey bee valuable as a producer but it is also one of the most beneficial of insects in cross-pollinating the flowers of various economic plants

Bee keeping is also extremely fascinating to the majority of people as a pastime, furnishing outdoor exercise as well as intimacy with an insect whose activity has been a subject of absorbing study from the earliest times It has the advantage of being a recreation which pays its own way and often produces no mean profit

It is a mistake however to paint only the bright side of the picture and leave it to the new bee keeper to discover that there is often another side Where any financial profit is derived bee keeping requires hard work and work at just the proper time otherwise the surplus of honey may be diminished or lost Few lines of work require more study to insure success In years when the available nectar is limited surplus honey is secured only by judicious manipulations and it is only through considerable experience and often by expensive reverses that the bee keeper is able to manipulate properly to save his crop Anyone can produce honey in seasons of plenty but these do not come every year in most locations and it takes a good bee keeper to make the most of poor years When even with the best of manipulations the crop is a failure through lack of nectar the bees must be fed to keep them from starvation

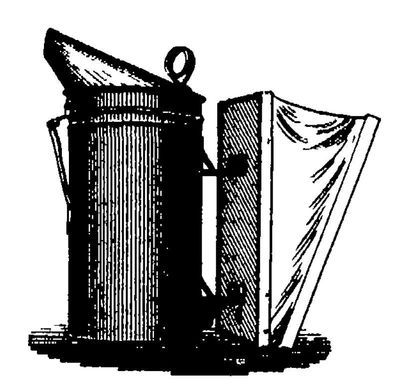

Fig 3 —Smoker

The average annual honey yield per colony for the entire country under good management, will probably be 25 to 30 pounds of comb honey or 40 to 50 pounds of extracted honey The money return to be obtained from the crop depends entirely on the market and the method of selling the honey If sold direct to the consumer extracted honey brings from 10 to 20 cents per pound and comb honey from 15 to 25 cents per section If sold to dealers, the price varies from 6 to 10 cents for extracted honey and from 10 to 15 cents for comb honey All of these estimates depend largely on the quality and neatness of the product. From the gross return must be deducted from 50 cents to $1 per colony for expenses other than labor including foundation sections, occasional new frames and hives and other incidentals not however providing for increase

Above all it should be emphasized that the only way to make bee keeping a profitable business is to produce only a first-class article. We can not control what the bees bring to the hive to any great extent, but by proper manipulations we can get them to produce fancy comb honey or if extracted honey is produced it can be carefully cared for and neatly packed to appeal to the fancy trade Too many bee keepers, in fact the majority, pay too little attention to making their goods attractive They should recognise the fact that of two jars of honey one in an ordinary fruit jar or tin can with a poorly printed label, and the other in a neat glass jar of artistic design with a pleasing attractive label the latter will bring double or more the extra cost of the better package It is perhaps unfortunate but nevertheless a fact, that honey sells largely on appearance and a progressive bee keeper will appeal as strongly as possible to the eye of his customer

Fig 4 —Bee Veil with Silk tulle Front

LOCATION OF THE APIARY

The location of the hives is a matter of considerable importance As a rule it is better for hives to face away from the prevailing wind and to be protected from high winds In the North a south slope is desirable It is advisable for hives to be so placed that the sun will strike them early in the morning so that the bees become active early in the day and thus gain an advantage by getting the first supply of nectar It is also advantageous to have the hives shaded during the hottest part of the day so that the bees will not hang out in front of the hive instead of working They should be so placed that the bees will not prove a nuisance to passers-by or disturb livestock This latter precaution may save the bee keeper considerable trouble for bees sometimes prove dangerous, especially to horses

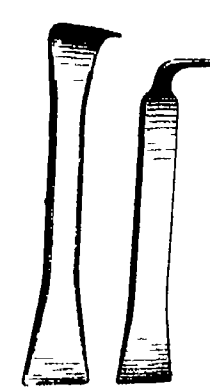

Fig 5 —Hive Tools

The plot on which the hives are placed should be kept free from weeds, especially in front of the entrances. The hives should be far enough apart to permit of free manipulation If hives are too close together there is danger of bees entering the wrong hive on returning especially in the spring

These conditions which may be considered as ideal, need not all be followed When necessary bees may be kept on house tops in the back part of city lots, in the woods, or in many other places where the ideal conditions are not found As a matter of fact, few apiaries are perfectly located, nevertheless, the location should be carefully planned especially when a large number of colonies are kept primarily for profit.

As a rule, it is not considered best to keep more than 100 colonies in one apiary and apiaries should be at least two miles apart. There are so many factors to be considered, however, that no general rule

* Farmer's Bulletin No 397 United States Department of Agriculture

can be laid down The only way to learn how many colonies any given locality will sustain is to study the honey flora and the record of that place until the bee keeper can decide for himself the best number to be kept and where they shall be placed

The experience of a relatively small number of good bee keepers in keeping unusually large apiaries indicates that the capabilities of the average locality are usually underestimated The determination of the size of extensive apiaries is worthy of considerable study for it is obviously desirable to keep bees in as few places as possible to save time in going to

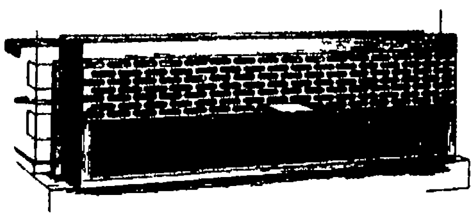

Fig 6 —Drone and Queen Trap on Hive Entrance

them and also expense in duplicated apparatus To the majority of bee keepers this problem is not important for most persons keep but a small number of colonies. This is perhaps a misfortune to the industry as a whole for with fewer apiaries of larger size under the management of careful trained bee keepers the honey production of the country would be marvelously increased For this reason professional bee keepers are not favorably inclined to the making of thousands of amateurs who often spoil a location for a honey producer and more often spoil his market by the injudicious selling of honey for less than it is worth or by putting on the market an inferior article

Out apiaries or those located away from the main apiary should be so located that transportation will be as easy as possibe The primary consideration however must be the available nectar supply and the number of colonies of bees already near enough to draw on the resources The out apiary should also be near to some friendly person so that it may be protected against depredation and so that the owner may be notified if anything goes wrong It is especially desirable to have it in the partial care of some person who can hive swarms or do other similar things that may arise in an emergency The terms under which the apiary is placed on land belonging to some one else is a matter for mutual agreement There is no general usage in this regard

EQUIPMENT IN APPARATUS

It must be insisted that the only profitable way to keep bees is in hives with movable frames The bees build their combs in these frames which can then be manipulated by the bee keeper as necessary The keeping of bees in boxes hollow logs or straw skeps is not profitable is often a menace to progressive bee keepers and should be strongly condemned Bees in box hives (plain boxes with no frames and with combs built at the will of the bees) are too often seen in all parts of the country The owners may obtain from them a few pounds of inferior honey a year and carelessly continue in the antiquated practice In some cases this type of bee keeping does little harm to others but where diseases of the brood are present the box hive is a serious nuisance and should be abolished

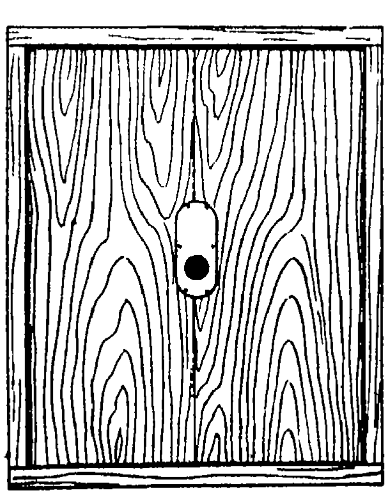

Fig 7 —Bee Escape for Removing Bees from Supers

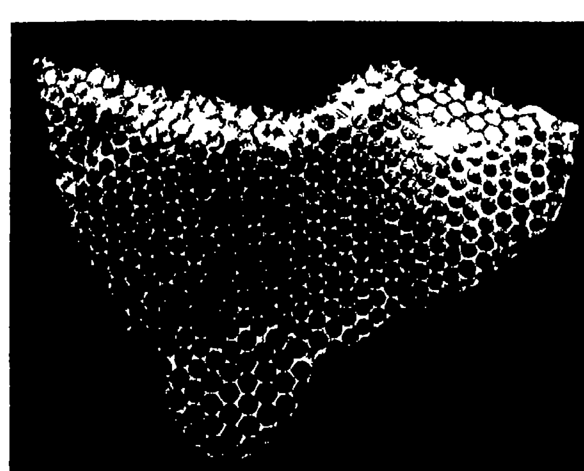

Fig 10 —Piece of Comb Showing Worker and Dr r Cells with Irregular Transit ons Red iced

HIVES.

It is not the purpose of this bulletin to advocate the use of any particular make of hive or other apparatus Some general statements may be made however, which may help the beginner in his choice

The type of hive most generally used in this country Fig. 2) was invented by Langstroth in 1851 It consists of a plain wooden box holding frames hung from [illegible] at the top and not touching the sides, top, [illegible] Hives of this type are made to hold from eight frames upward The size of frame in general use, known as the Langstroth (or L) frame (9⅛ by 17⅝ inches) is more widely used than all others combined The number of frames used depends on the kind of honey produced (whether comb or extracted) and on the length of honey flow and other local factors There are other hives used which have points of superiority These will be found discussed in the various books on bee keeping and in the catalogues of dealers in bee keepers supplies

Whatever hive is chosen there are certain points of importance which should be insisted on The material should be of the best the parts must be accurately made so that all frames or hives in the apiary are interchangeable All hives should be of the same style and size they should be as simple as it is possible to make them to facilitate operation Simple frames diminish the amount of propolis, whi h will interfere with manipulation As a rule it is better to buy hives and frames from a manufacturer of such goods rather than to try to make them unless one is a good wood worker

The choice of a hive while important, is usually given undue prominence in books on bees In actual practice experienced bee keepers with different sizes and makes of hives under similar conditions do not find as much difference in their honey crop as one would be led to believe from the various published accounts

HIVE STANDS

Generally it is best to have each hive on a separate stand The entrance should be lower than any other part of the hive Stands of wood bricks tile (Fig 2) concrete blocks or any other convenient material will answer the purpose The hive should be raised above the ground so that the bottom will not rot It

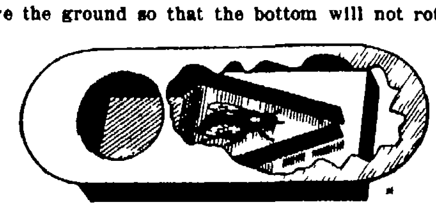

Fig 8 S[illegible] Bee Es[illegible]pe

is usually not necessary to raise the hive more than a few inches Where ants are a nuisance special hive stands are sometimes necessary

OTHER APPARATUS

In addition to the hives in which the bees are kept some other apparatus is necessary A good smoker (Fig 3) consisting of a tin or copper receptacle to hold burning rotten wood or other material with a bellows attached is indispensable A veil of black material preferably with a silk t ille front (Fig 4) should be used Wire-cloth veils are also excellent Even if a veil is not always used it is desirable to have one at hand in case the bees becom cross Cloth or leather gloves are sometimes used to protect the hands but they hinder most manipulations Some sort of tool (Fig 5) to pry hive covers loose and frames apart is desirable A screw driver will answer but any of the tools especially for that purpose is perhaps better Division boards drone traps (Fig 6) bee escapes (Figs 7 and 8) feeders (Figs 14 15 16 17) foundation fasteners wax extractors bee brushes (Fig. 9) queen rearing outfits and apparatus for producing comb or extracted honey (Figs 2 18 19) will be found described in catalogues of supplies a full discussion of these implements would require too much space in this bulletin A few of these things are illustrated and their use will be evident to the bee keeper It should be remembered that manipulation based on a knowledge of bee activity is of far greater importance than any particular style of apparatus, and in a short discussion like the present it should be given more space especially since supply dealers will be glad to furnish whatever information is desired concerning apparatus

EQUIPMENT IN BEES

As stated previously it is desirable to begin bee keeping with a small number of colonies In purchasing these it is usually best to obtain them near at home rather than to send to a distance for there is considerable liability of loss in shipment. Whenever possible it will be better to get bees already domiciled in the particular hive chosen by the bee keeper as the best but if this is not practicable then bees in any hives or in box hives may be purchased and transferred It is a matter of small importance

Fig 9 Bee Brush

what race of bees is purchased for queens of any race may be obtained and introduced in place of the original queen and in a short time the workers will all be of the same race as the introduced queen This is due to the fact that during the season worker bees die rapidly and after requeening they are replaced by the offspring of the new queen

A most important consideration in purchasing colonies of bees is to see to it that they are free from disease In many States and counties there are inspectors of apiari s wl o an l e ns l l o this point but if this is not possible even a novice can tell whether or not there is anything wrong with the brood and it is always safest to refuse hives containing dead brood

The best time of the year to begin bee keeping is in the spring for during the first few months of ownership the bee keeper can study the subject and learn what to do so that he is not so likely to make a mistake which will end in loss of bees It is usually best to buy good strong colonies with plenty of brood for that season of the year but if this is not practicable then smaller colonies or nuclei may be purchased and built up during the season Of course no surplus honey can be expected if all the honey gathered goes into the making of additional bees It is desirable to get as little drone comb as possible and a good supply of honey in the colonies purchased

The question as to what race and strain of bees is to be kept is important If poor stock has been purchased locally the bee keeper should send to some reliable queen breeder for good queens as a foundation for his apiary Queens may be purchased for $1 each for untested to several dollars each for select ed breeding queens Usually it will not pay beginners to buy selected breeding queens for they are not yet prepared to make the best use of such stock Untested or tested queens are usually as good a quality as are profitable for a year or so and there is also less danger in mailing untested (young) queens

Various races of bees have been imported into the United States and among experienced bee keepers there are ardent advocates of almost all of them The black or German race was the first imported very early in the history of the country and is found every where but usually not entirely pure As a rule this race is not desirable No attention has been paid to breeding it for improvement in this country and it is usually found in the hands of careless bee keepers As a result it is inferior although it often produces beautiful comb honey

The Italian bees the next introduced are the most popular race among the best bee keepers in this country and with good reason They are vigorous work

ers and good honey gatherers defend their hives well and above all have been more carefully selected by American breeders than any other race Especially for the last reason it is usually desirable to keep this race That almost any other race of bees known could be bred to as high a point as the Italians and perhaps higher can not be doubted but the bee keeper now gets the benefit of what has been done for this race It should not be understood from this that the efforts at breeding have been highly successful On the contrary bee breeding will compare very unfavorably with the improvement of other animals or plants which have been the subject of breeding investigations

Italian bees have been carefully selected for color by some breeders to increase the area of yellow on the abdomen until we now have what are known as five banded bees These are very beautiful but it can scarcely be claimed that they are improved as honey producers or in regard to gentleness They are kept mostly by amateurs

Some breeders have claimed to select Italians for greater length of tongue with the object of getting a bee which could obtain the abundance of nectar from red clover If any gain is ever made in this respect it is soon lost The terms red clover bees or long tongued bees are somewhat misleading but are ordinarily used as indicating good honey producers

Caucasian bees recently distributed throughout the country by this Department are the most gentle race of bees known They are not stingless however as is often stated in newspapers and other periodicals Many report them as good honey gatherers They are more prolific than Italians and may possibly become popular Their worst characteristic is that they gather great quantities of propolis and build burr and brace combs very freely They are most desirable bees for the amateur or for experimental purposes

Carniolan and Banat bees have some advocates and are desirable in that they are gentle Little is known of Banats in this country Carniolans swarm excessively unless in large hives Cyprians were formerly used somewhat but are now rarely found pure and are undesirable either pure or in crosses because of the fact that they sting with the least provocation and are not manageable with smoke They are good honey gatherers but their undesirable qualities have caused them to be discarded by American bee keepers Holy land Egyptian and Tunic (Tunisian) bees have also been tried and have been universally abandoned

BEE BEHAVIOR

The successful manipulation of bees depends entirely on a knowledge of their habits This is not generally recognized and most of the literature on practical bee keeping consists of sets of rules to guide manipulations This is too true of the present paper but is due to a desire to make the bulletin short and concise While this method usually answers it is nevertheless faulty in that without a knowledge of fundamental principles of behavior the bee keeper is unable to recognize the seemingly abnormal phases of activity and does not know what to do under such circumstances Rules must of course be based on the usual behavior By years of association the bee keeper almost unconsciously acquires a wide knowledge of bee behavior and consequently is better able to solve the problems which constantly arise However it would save an infinite number of mistakes and would add greatly to the interest of the work if more time were expended on a study of behavior then the knowledge gained can be applied to practical manipulation

A colony of bees consists normally of one queen bee the mother of the colony and thousands of sexually undeveloped females called workers which normally lay no eggs but gather the stores keep the hive clean feed the young and do the other work of the hive During part of the year there are also present some hundreds of males or drones (often removed or restricted in numbers by the bee keeper) whose only service is to mate with young queens These three types are easily recognized even by a novice In nature the colony lives in a hollow tree or other cavity, but under manipulation thrives in the artificial hives provided The combs which form their abode are composed of wax secreted by the workers The hexagonal cells of the two vertical layers constituting each comb have interplaced ends on a common septum In the cells of these combs are reared the developing bees and here are stored honey and pollen for food

The cells built naturally are not all of the same size those used in rearing worker bees being about one fifth of an inch across and those used in rearing drones and in storing honey about one fourth of an inch across (Fig 10) The storage cells are more irregular and generally curve upward at the outer end Under manipulation the size of the cells is controlled by the bee keeper by the use of comb foundation—sheets of pure beeswax on which are impressed the bases of cells and on which the bees build the side walls

In the North when the activity of the spring begins the normal colony consists of the queen and some thousands of workers As the workers bring in early pollen honey the queen begins to lay eggs in the worker cells These in time develop into white larvæ which grow to fill the cells They are then capped over and transform gradually into adult worker bees As the weather grows warmer and the colony increases in size by the emergence of the developing bees the quantity of brood is increased The workers continue to bring in pollen and nectar to be made into honey After a time the queen begins to lay eggs in the larger cells and these develop into drones or males

Continued increase of the colony would result in the formation of enormous colonies and unless some division takes place no increase in the number of colonies will result Finally however the workers begin to build queen cells over certain female larvæ These are larger than any other cells in the hive and hang on the comb vertically In size and shape they may be likened to a peanut and are also rough on the outside When the larvæ in these cells have grown to full size they are sealed up and the colony is then ready for swarming

Swarming consists of the exit from the hive of the original queen with part of the workers They leave the hive to seek a new home and begin the building of combs storing of honey and pollen and rearing of brood in a new location They leave behind the honey stores except such as they can carry in their honey stomachs and the brood some workers and no adult queen but several queen cells from which will later emerge young queens By this interesting process the original colony is divided into two

The swarm finds a new location either in a hollow tree or if cared for by the bee keeper in a hive The workers build new combs the queen begins laying and in a short time the colony is again in normal condition

The colony on the old stand (parent colony) has the advantage of the bees which emerge from the brood After a time (usually about nine days) the queens in their cells are ready to emerge. If the colony is only moderately strong the first queen to emerge is allowed by the workers to tear down the other queen cells and kill the queens not yet emerged but if a second swarm is to be given off the queen cells are protected

If the weather permits after from five to eight days the young queen flies from the hive to mate with a drone Mating usually occurs but once during the life of the queen and always takes place on the wing In this single mating she receives enough spermatozoa to last throughout her life She returns to the hive after mating and in about two days begins egg laying The queen never leaves the hive except at mating time or with a swarm and her sole duty in the colony is to lay eggs to keep up the population

When the flowers are in bloom which furnish most nectar the bees usually gather more honey than they need for their own use, and this the bee keeper can safely remove They continue the collection of honey and other activities until cold weather comes on in the fall when brood rearing ceases, they then become relatively quiet remaining in the hive all winter except for short flights on warm days When the main honey flow is over the drones are usually driven from the hive By that time the virgin queens have been mated and drones are of no further use They are not usually stung to death but are merely carried or driven from the hive by the workers and starve A colony of bees which for any reason is without a queen does not expel the drones

Many abnormal conditions may arise in the activity of a colony and it is therefore necessary for the bee keeper to understand most of these so that when they occur he may overcome them If a virgin queen is prevented from mating she generally dies but occasionally begins to lay eggs after about four weeks In this event however all of the eggs which develop become males Such a queen is commonly called a drone-layer

If the virgin queen is lost while on her flight or the colony at any other time is left queenless without means of rearing additional queens it sometimes happens that some of the workers begin to lay eggs These eggs also develop only into drones

It also happens at times that when a queen becomes old her supply of spermatozoa is exhausted at which time her eggs also develop only into drones These facts are the basis of the theory that the drone of the bee is developed from an unfertilized egg or is parthenogenetic A full discussion of this point is impossible at this time

The work of the hive is very nicely apportioned among the inmates so that there is little lost effort As has been stated the rearing of young is accomplished by having one individual to lay eggs and numerous other (immature females) to care for the larvæ In like manner all work of the colony is apportioned In general it may be stated that all inside work—wax building care of brood and cleaning—is done by the younger workers those less than seventeen days old while the outside work of collecting pollen and nectar to be made into honey is done by the older workers This plan may be changed by special conditions For example if the colony has been queenless for a time and a queen is then given old workers may begin the inside work of feeding larvæ and these may also secrete wax Or if the old workers are all removed the younger bees may begin outside work As a rule however the general plan of division of labor according to age is followed rather closely

(To be continued)

Physical Anomalies of Water

WATER is a paradoxical and unique substance A thermometer filled with water instead of mercury or alcohol gives reliable indications of moderate temperatures but when it is cooled below 4 deg C (about 39 deg F) it ceases to fall and begins to rise and at the freezing point (0 deg C or 32 deg F) it stands at the same height as at 8 deg C (about 46½ deg F) In other words water attains its maximum density at 4 deg C and when it is cooled below this point it expands instead of contracting In the act of freezing another and a sudden expansion takes place which is the opposite of what occurs in the solidification of most substances Hence ice floats on water a fact of immense geological and biological importance which prevents lakes and streams from freezing solid and preserves the animal and vegetable organisms which they contain In all latitudes and at all seasons the temperature at great depths in the ocean is approximately 4 deg C

The compressibility viscosity and specific heat of water exhibit corresponding anomalies all of which have been attributed by Roentgen to a common cause Roentgen assumed that water even at ordinary temperatures contains a variable number of polymonized or agglutinated molecules probably identical with the molecules of ice or that water may be regarded as a solution of ice as syrup is a solution of sugar The number of these complex molecules diminishes as the temperature rises

This view is supported by the measurements of Ramsay and Shields who account for the peculiar properties of water by the presence of associated molecules

A note in *Cosmos* states that Duclaux from his recent study of this theory concludes in agreement with Sutherland that the molecule of ice is probably found by the combination of three molecules of water or that the molecular weight of ice is 54 and its chemical formula is $(H_2O)_3$

Destruction of Concrete by Hydrogen Sulphide

THE rapid disintegration of the concrete walls of sewage basins has often been observed The German journal *Beton und Eisen* give an account of Stephan's investigation of the deterioration observed in the concrete vaulted roof of a sewage sedmentation basin As the crude sewage smelled strongly of hydrogen sulphide while none of this gas was found either in the clarified sewage or in the air beneath the vault, Stephan concluded that the hydrogen sulphide disengaged by the sewage was entirely absorbed by the concrete and was the cause of the observed corrosion.

Hydrogen sulphide can destroy concrete by combining with its lime to form calcium sulphide which may then be converted into soluble calcium bisulphide or oxidized to soluble calcium sulphate The analysis of specimens of the concrete of the vault confirmed these conclusions but showed, also that part of the drainage was due to the presence of carbon dioxide and the consequent formation of soluble calcium bicarbonate

Stephan suggests a very simple method of preventing corrosion by coating with tar after the concrete has hardened all parts of the wall that are exposed to the contact of injurious gases

The Railophone

THE various systems which have been devised for telephoning to and from moving railway trains have, as a rule proved unsatisfactory A new system, invented by Von Kramer and bearing the queer name railophone," has been employed with success on the line connecting London with Brighton A large coil of wire is placed on the roof of the car with its plane vertical and parallel to the rails, and its ends are connected to a telephone receiver installed in a sound proof cabinet inside the car This coil is inductively affected by a fixed circuit composed of an overhead telegraph wire and a cable buried beside the rail, and connected with a telephone transmitter at a station A circuit of this kind is provided for each track.

INDEX OF INVENTIONS

For which Letters Patent of the United States were Issued for the Week Ending February 7, 1911,

AND EACH BEARING THAT DATE

[See note at end of list about copies of these patents.]

A printed copy of the specification and drawing of any patent in the foregoing list, or any patent in print issued since [illegible] will be furnished from this office for [illegible] provided the name and number of the patent desired and the date be given. Address Munn & Co., Inc., 361 Broadway, New York.

Canadian patents may now be obtained by the inventors for any of the inventions named in the foregoing list. For terms and further particulars address Munn & Co. Inc., 361 Broadway, New York.

How Sea Water Freezes

Arctowski has made a series of interesting observations of the congelation of sea water. By lying down beside a hole cut in the ice formed on sea water he was enabled to view at short range the formation of new ice close to the wall of ice surrounding the hole. At the surface of the water thin hexagonal plates of ice gradually developed in delicate fern like forms and grew by attracting to themselves minute crystals which formed spontaneously in the moving water. The formation of these crystals increased the density of portions of the water so that the liquid filaments of different densities were made visible by refraction as in a non homogeneous mixture of alcohol and water. The floating hexagonal plates attained diameters ranging from ⅓ inch to 1½ inches and grouped themselves together irregularly leaving interstices usually of triangular form.

At a depth of 6 or 8 inches below the surface of the water leaf like forms from 4 to 10 inches long and with serrated edges subsequently grew from the ice surrounding the hole. The planes of these leaves were usually vertical and their axes horizontal.

The quantity of salt in sea water ice is variable. One specimen contained 2 parts in 10 000 while the water in the vicinity contained 323 parts in 10 000. Another specimen showed 114 parts in 10 000 but when some of the same ice was partially melted very slowly the remaining portion was found to contain only 16 parts of salt in 10 000.

State Report on Oil and Gas Development in Tennessee

By George H Ashley State Geologist

The State Geological Survey has just gotten out a report on the development of the oil and gas industry in Tennessee. The report which is short and preliminary in nature is by Mr M J Munn oil and gas expert of the United States Geological Survey and describes the result of work done by him last summer in co operation with the State Survey. It describes the early finding of oil and gas in Overton and Fentress counties the striking of gushers there the decline of fields and the abandonment of many of them. Then the counties of middle and west Tennessee are taken up in order, and the developments of each described. The report does not go at length into the geology of the oil and gas deposits of the State that being left to a fuller report which it is planned to prepare within the next one or two years.

In the final chapter Mr Munn discusses the future possibilities of Tennessee as an oil and gas State. Long experience has indicated that the Great Valley of Tennessee lying east of the Cumberlands is not an oil and gas territory as drilling from Pennsylvania to Alabama in that belt has universally resulted in commercial failures. He also condemns the rocks of the middle basin of Tennessee as probably non-oil producing based simply upon the fact that the rocks occurring in the center of that basin are lower stratigraphically than any rocks that have yet produced oil in commercial quantities. While this is only negative evidence yet in view of the large number of wells which have been drilled in rocks of that age so far without result, the evidence is not encouraging. The Cumberland Plateau Mr Munn considers much more hopeful and especially the western edge and possibly also the Highland Rim region between the central basin and the Cumberlands. The Highland Rim region in the western part of middle Tennessee is also considered to be possibly an oil and gas territory.

In west Tennessee no commercial oil or gas has yet been obtained but the conditions are considered as hopeful especially along the crest of the divide between the Tennessee-Mississippi rivers.

In general Mr Munn finds that Tennessee is producing no oil and gas to-day in commercial quantities beyond a few wells that hardly pay interest on their investments. In a few cases gas wells are supplying one or two houses with gas or form the source of gas being burned in flambeau. Of the large number of wells drilled in this State the great majority have been "dry holes" or unproductive. Nearly all of these holes however report shows of oil or gas suggesting that there may be a large quantity of those substances in the rocks. A study of the situation suggests that the difficulty is the lack of porous rock or rocks that may serve as reservoirs. In practically all of the oil fields, the oil and gas is found in porous sandstones and limestones the pores being large enough to allow the ready flow of oil or gas. This being of course only one of the conditions under which a flow is obtained and as far as can be ascertained over much of this State, rocks of that character so situated as to hold oil or gas are lacking. In the case of the past oil and gas production in the Cumberlands most of it appears to have come from crevices in a limestone near the surface.

In an appendix the State Geologist discusses results of recent drilling in West Tennessee. He compares the conditions there with those in Louisiana and Texas, where oil and gas have been found, and concludes that while no oil and gas have been found in West Tennessee, and while the peculiar salt dome conditions existing in Louisiana and Texas which have produced most of the gushers of those States, probably do not exist in Tennessee, yet that it is possible or probable that some oil and gas may be found there but that it may require the drilling of nine or ninety nine "dry wells" before one producing well is found. that the search for oil and gas in West Tennessee at the present stage of the game is only a gamble, in which no one should play who cannot afford to lose and lose heavily without feeling it, in the prospect of ultimately striking oil and recovering all that they have expended and then some.

The students of the School of Engineering at the Pennsylvania State College are erecting a wireless telegraph station designed for communication with the stations at Washington, New York, Philadelphia, Boston and elsewhere. Among the uses which will be made of the apparatus reporting football matches played by the college team in other cities where suitable wireless telegraphic equipments have been erected may be mentioned. A level circular track, 200 feet in diameter for making tests upon aeroplanes and propellers has also been erected. A car driven by an electric motor will run upon this track at speeds up to 60 miles per hour. To this car will be attached the planes or propellers to be tested. The frictional resistance or lifting power of the planes and the propelling force and efficiency of propellers will be determined by a series of dynamometers, recording the results obtained by electrical means on instruments placed upon a platform at the center of the circular track. The problem of plane shape and surface can be readily studied by this apparatus as can also data relating to the shape size and speed of the propellers.

Important AND Instructive Articles on AVIATION

In the Scientific American Supplement we have published in the past few years papers by some of the more eminent physicists and engineers on flying machines. No book thus far published is so complete and so authoritative as these articles. The range of the articles is wide, covering as it does the theoretical side of aviation as well as those more practical aspects which deal with the construction of machines. The following is a partial list of the more important articles which have appeared in the Scientific American Supplement, see special note below.

Nos. 1816 1817 1818 1819 1820, 1821 and 1822 THE PRACTICE AND THEORY OF AVIATION
By Grover Cleveland Loening, A. M.

This is the most compact paper on aeroplanes that has probably ever been published. Fourteen biplanes and monoplanes are described in detail and illustrated with scale drawings namely the Farman, Cody, Curtiss, Wright Voisin (old model) Voisin (new model), and Summer biplanes, and the Antoinette, Santos Dumont, Bleriot XI, Bleriot XII, Grade, Pfitzner monoplanes. The proper dimensioning of aeroplane surfaces as deduced by famous experimenters from their tests is also considered. Taken as a whole, this series of seven papers constitutes an admirable text book.

No. 1713 THE WRIGHT AEROPLANE

This is a thorough description of the old type of Wright biplane with the horizontal elevation rudder in the front of the machine. Excellent diagrams and photographic views accompany the paper.

No. 1756. LOIS BLERIOT AND HIS AEROPLANES

Few people realize that Bleriot's successful monoplane is the result of ten years of daring and perilous experiment. In this paper will be found an instructive description of the evolution of the present successful Bleriot monoplane, illustrated with diagrams and photographs.

No. 1788. THE FARMAN BIPLANE

A complete description of the Farman biplane, with detail drawings of the box tail and vertical rudders, the manner of working the four ailerons, hand and foot levers which control the machine, plan view and side elevation of the entire machine.

No. 1767 THE SANTOS-DUMONT MONOPLANE

An illustrated article describing the Demoiselle, the smallest and one of the fastest machines thus far made. Sketches accompany the article, showing the details of the construction and control.

No. 1882. HOW TO MAKE A GLIDING MACHINE

Full details and drawings which will enable any one to make a glider for $15 00

ALL THESE ARTICLES ARE PROFUSELY ILLUSTRATED

Each number of the Supplement costs 10 cents, mailed, and you can order as many of them as you wish. A set of papers containing all the articles above mentioned will be mailed for $1 20

SPECIAL NOTE: *We will mail (gratis) a list of many additional important papers in the Supplement, treating of aeronautics. Ask for list "A."*

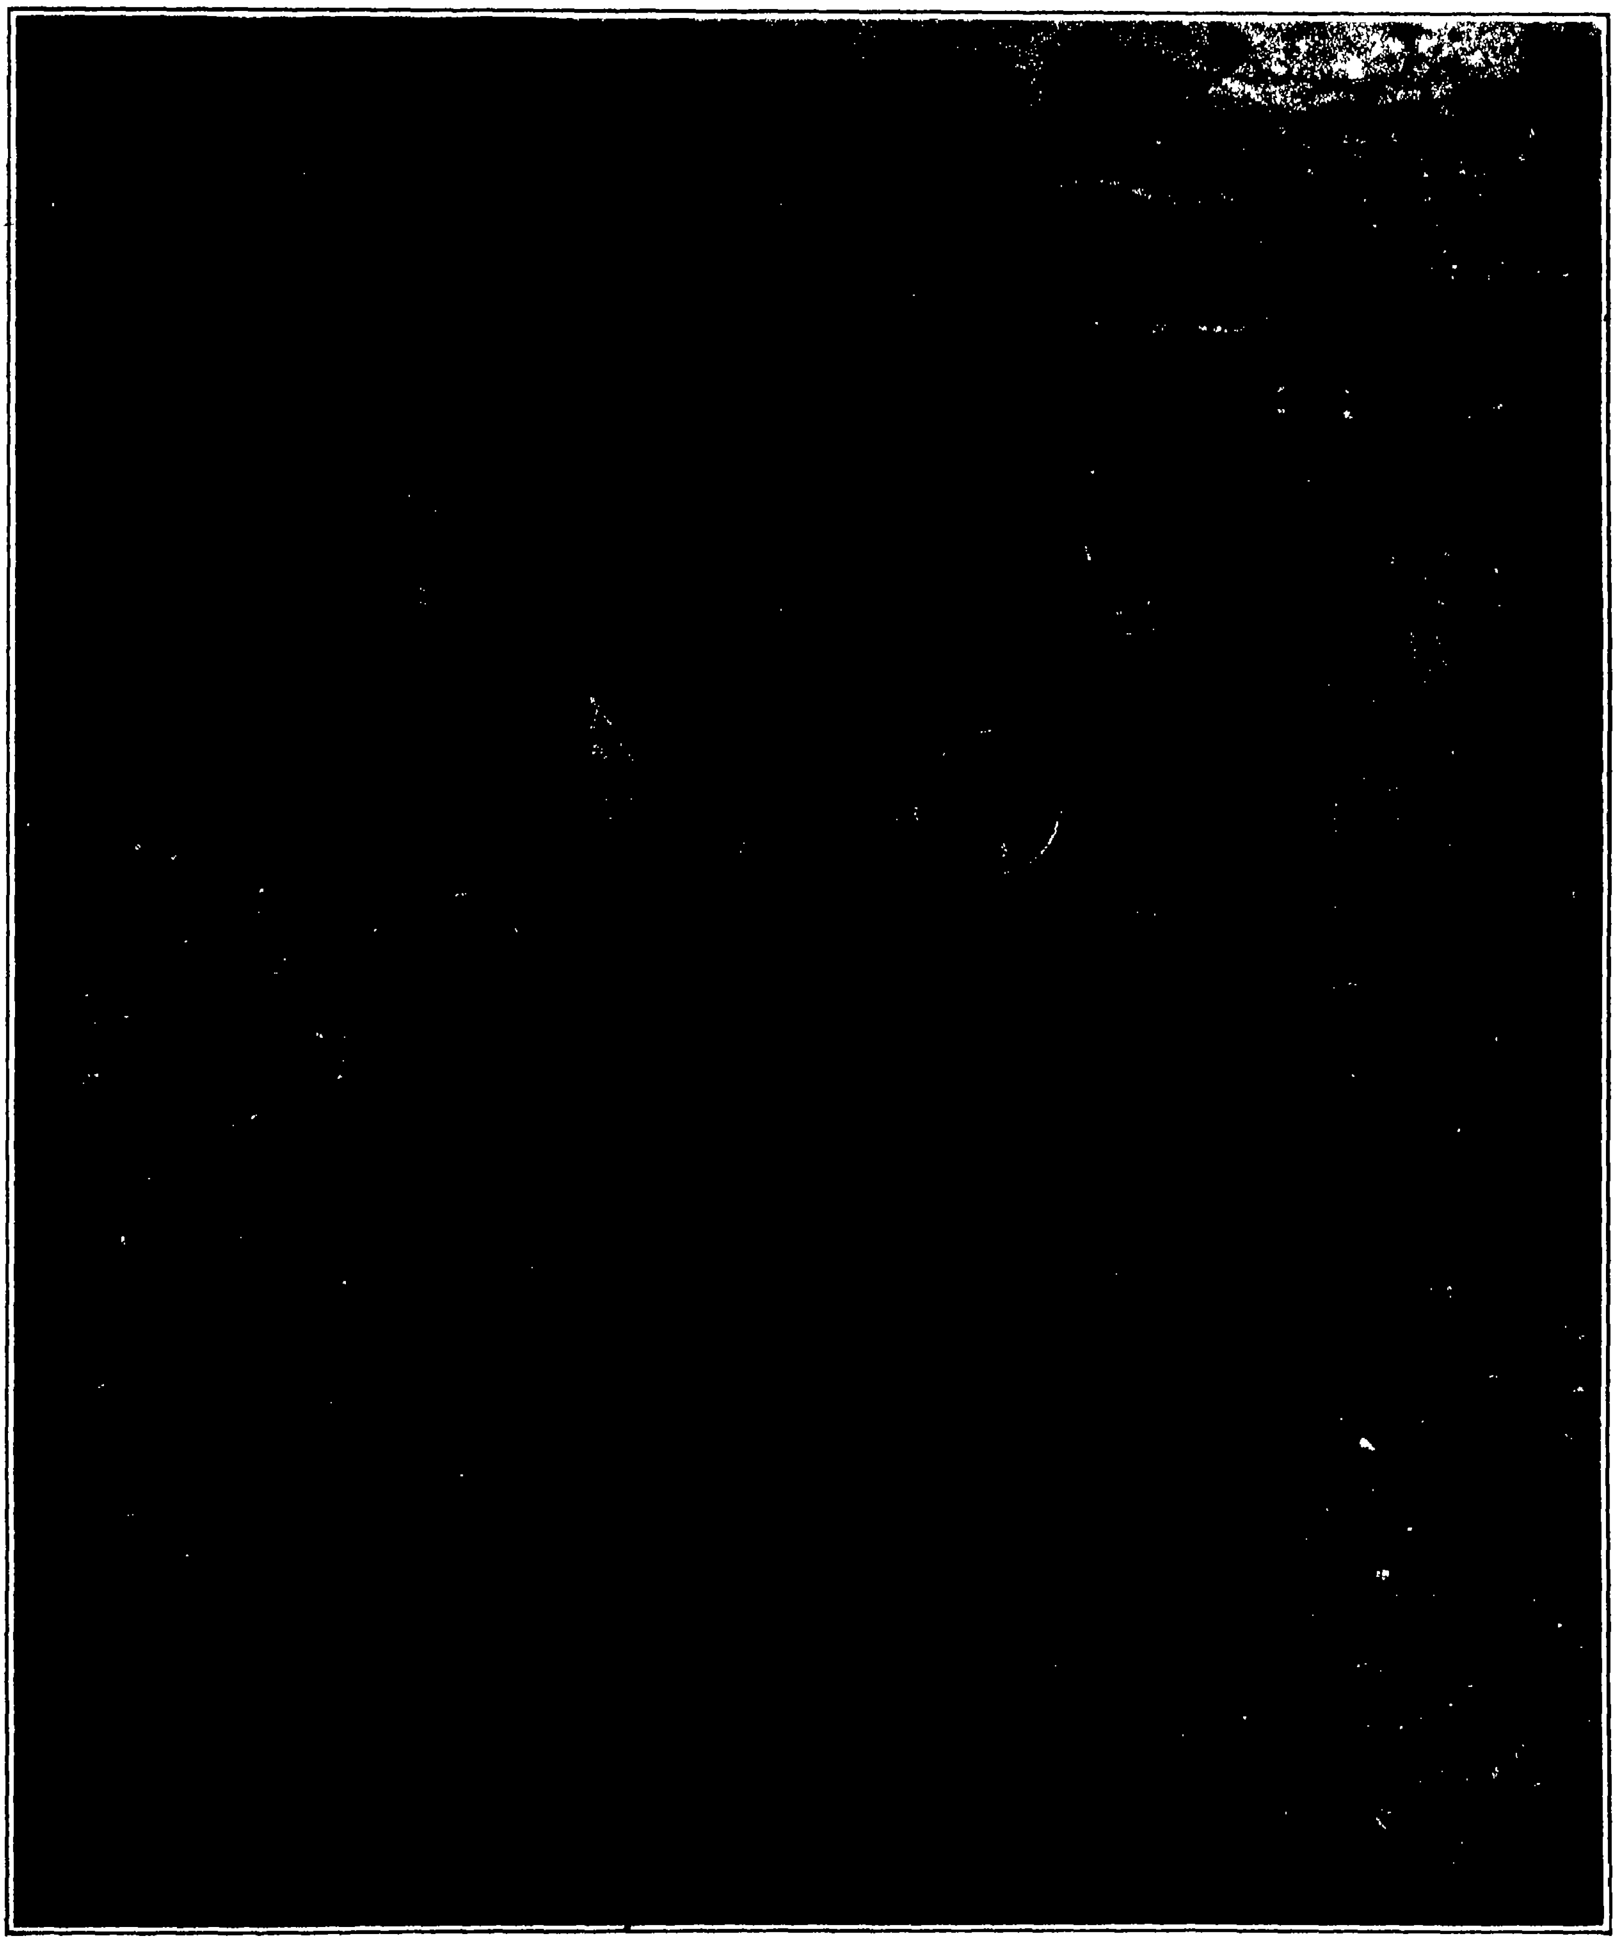

FIG 1—TEN-TON ELECTRIC LOCOMOTIVE IN A COAL MINE

MODERN COAL-CUTTING MACHINERY AND MINE RAILWAYS —[See page 120]

Production of Low Temperature and Refrigeration—II*

The First International Congress of Refrigerative Industries

By L. Marchis

Concluded from Supplement No 1833, page 103

COLD STORAGE ROOMS are cooled by different methods. In the first place one of the most common methods is to direct dry cold air into the preserving rooms. This air is brought down to a low temperature and sufficiently dried out either by passing over a cold saline solution (spray refrigerator) or by circulation in contact with a coil acting as refrigerant (dry refrigerator). The choice of the type of refrigerator as M Barrier has said is a question of circumstances. Even in the case of meat preservation it makes a difference whether the meat is frozen, that is to say immunized, or whether it is merely refrigerated (brought to a temperature between zero and 4 deg C) where it is more particularly subject to the action of harmful germs. It also makes a difference whether it is a military storehouse where the meat is only taken out for immediate consumption and the refrigerating chambers are closed up to the time the food is removed or whether it is a commercial storehouse where the meat is taken in or brought out daily and is more or less exposed to the air and where the frequent entries of the workmen carry in noxious gases and impurities. In this latter case the spray evaporator appears preferable on account of the purification and asepsis of the air of the chambers. In the first case however the dry evaporator on account of its greater simplicity and the lowering of the concentration of the brine presents some real advantages.

It is not sufficient only to produce cold; the cold must be conserved. For this reason the insulation from heat should be considered a question of the first importance in the construction of a cold store. The proper conservation of the contents demands that the temperature of the storage chambers should be as constant as possible. The question of insulating materials therefore has been a subject of particular attention by the congress.

A good heat insulator should fulfill the following conditions:

(1) It should be a very poor conductor of heat. If a very thin layer of the insulator is sufficient to obtain proper insulation the result is both economy of space and economy of the insulating material.

(2) It should have a low specific gravity. This condition is important in insulation installment aboard ship. Its importance is not less however in cold storage warehouses because of the reduction of cost in transporting it to the work and the possibility of economy in the cost of construction by making possible the construction of very lightly built buildings.

(3) The insulator should be free from odor and not subject to decomposition even when moist. This condition is all important in the construction of cold storage houses designed for the preservation of food stuffs. These absorb very easily bad odors arising from the fermentation of insulating material and become unfit for consumption. For this reason such substances as rice husks, cut straw, oat husks or cork mixtures made with fermentable substances such as casein, should be rejected.

(4) The insulating material should absorb to as great a degree as possible the bad odors which are set free in refrigerating chambers and render them less harmful. From this point of view peat or turf some times is of great service.

(5) The insulating material should not be hygroscopic. It should not absorb and retain moisture which is capable of causing it to lose its poor conducting qualities. This is the case with mineral wool, a sort of fibrous glass made out of the slag of blast furnaces.

(6) When by reason of circumstances such as the breaking of a water tube etc an insulating material is wet it should be able to dry out easily and regain its property of poor conduction.

(7) The insulating substances should not be attractive to parasites, mice, rats etc nor afford a good culture ground for microbes.

(8) The insulation material should be incombustible or at least should not propagate combustion started at any point of the mass. A certain number of cork mixtures possess this property, for example the mixture of cork and pitch. M Brüll has shown to the congress several different types of entirely fire-proof cork mixtures.

(9) When once placed in the packing which makes up the insulating mat either inside or outside of the wall the insulating material should not settle and thus produce continuous voids in the insulation. The different wood carbons included under the term charcoal are liable to this disadvantage when they are used without special precautions.

(10) The insulating materials should not attack the wood, iron or masonry which comes in contact with them.

(11) The insulating materials should be very easy to work and to apply to the walls of the storage chambers and should possess a certain resistance to bending or crushing.

(12) The insulation should not lose its qualities with time.

It is difficult enough to find an insulation that combines all these qualities. Cork either in granular form or agglomerated however is at present the most employed. M Pasquay has informed the congress that silk waste protected by an impermeable envelope forms an excellent insulation.

The knowledge of the co-efficient of conduction of insulators is of great importance with regard to the thickness which the protecting linings must be to bring down the loss of cold within a certain limit. Different methods have been proposed for determining this. In one of these the two faces of a plate of the substance are maintained constantly at different temperatures and the quantity of heat passing through the plate in a certain time determined. This may be accurately measured by weighing the amount of ice melted. This is the principle of the well known physical method called the wall method. It may perhaps be remarked that those who have used this method have not taken precautions against the loss of heat at the edges of the experimental plates. They have not made use of the method of using a guard ring in the form originated by M Berget.

The other methods for measuring the conductibility are based on Forbes method. This consists of heating one of the extremities of a long slender bar of the material to be tested. When the system has attained an equilibrium the temperature is taken at different points along the bar and by the formulæ of Fourrier the coefficient of conductibility can be calculated if that of emission is known. This latter may be that of a coating or a very thin layer of metal with which the bar has been previously provided.

A variation of the Forbes method is that of the sectional bar of Lodge. This bar is composed of three sections, the first and the third are of a metal the conductibility of which is known. The second is made up of the material to be tested. The end of the first section is heated and the progression of temperature when equilibrium is established is measured. The general formula for uniform movement of heat in an elongated bar makes possible the calculation of the conductibility of the material composing the second section.

It is this method that M Desvignes has used in determining the conductibility of several insulating substances. He has worked out the technique so that it can be easily employed in the refrigerating industry.

Some of the results obtained by this method are as follows:

Coefficient of Conductibility

	Calories for Meter-Degree Hour
Cork	0 05 to 0 014
Granular cork	068
Cork with casein binder	069
Cork with odorless pitch binder	087
Cork with sodium silicate binder	067
Cork mixed with infusorial earth and calcined	069

As M Desvignes has remarked it would perhaps be imprudent to take these figures as a basis for the calculation of loss in a cold-storage plant. The specimens which were used in the tests were picked and were perfectly dry. The given coefficients should be increased not less than 20 per cent. In the application to certain materials some account should be taken of the method of joining. Thus in a partition of cork bricks pointed by cement mortar where the joints represent in very careful work about 15 per cent of the total volume the coefficient of conductibility of the brick itself, referred to the total surface of the partition should be almost doubled. These considerations will show what a difficult question even the approximate calculation of the heating effect due to the walls of the refrigerator may be. The second section has withheld opinion on this question therefore and adopted the following resolutions:

(1) That study and research shall be undertaken in the technical schools and laboratories to determine either by known apparatus or that which shall be subsequently devised the specific constants of the different insulators which are practically utilizable in the refrigerating industry.

(2) That the characteristic properties and constants to be determined by account being taken in each case of the degree of humidity in the following:

The density to be employed.
The coefficient of conductibility.
The resistance to flexure.
The resistance to crushing.
The power of expelling water.
The power of absorbing odors.
The incombustibility.

These constants should be determined under conditions of temperature and thickness of material applicable to the refrigerating industry.

(3) That the second section shall call especial attention to the study of the conductibility as a function of temperature, thickness, degree of humidity and of other causes capable of influencing the conductibility, for example the state of division of the material necessary to assure a certain insulation.

(4) That the section requests that the International Bureau of the Refrigeration Congresses, the organization of which has been planned, shall constitute an international commission charged with taking up the study of methods of testing and co-ordinating with a view to establishing methods and obtaining comparable results any researches which are made in which otherwise the investigators would have their usual latitude.

(5) That it shall be of interest to submit the question of securing uniformity of such methods to the next congress if the researches concerned are sufficiently advanced.

Official instruction up to the present time has been somewhat neglectful of the refrigerating industry. The present-day developments of this industry render more and more necessary the education of engineers who are specialists in this line. For this reason the second section has also enacted the following resolutions:

(1) That theoretical and professional instruction applied to different present-day phases of the industry of refrigeration and with a view to new applications shall be inaugurated in the laboratories and higher technical schools of all countries, this course of instruction to be followed by detailed practical study of important refrigerating establishments and rational experimentation with the machinery there used under the direction of specialists.

(2) That in order that the necessary scientific equipment and experimental material and the cost of the experiments may be provided for this instruction should be subsidized by the governments, municipalities, chambers of commerce, industrial societies, agricultural syndicates and all other individually or collectively interested in the refrigeration industry.

(3) That the general work and the results of researches carried out in these laboratories and schools as well as those of associations of engineers and manufacturers who are working in refrigeration should be submitted to the permanent International Bureau and co-ordinated by it in order that it may publish periodically a bibliographical index and may compare the results and derive all the useful indications and conclusions possible from them for presentation to the next Congress of Refrigeration for its examination.

III THE CONSERVATION OF PERISHABLE ARTICLES

We have now found out how to produce and maintain a low temperature in cold stores. It remains now to study the methods of construction and use of the cold storage rooms, and the rules permitting of the conservation of different sorts of articles. These questions have been the subject of numerous reports and discussions which it would take too much time to digest here. I will, therefore, only indicate some of the most important conclusions on these questions.

The cold air of rooms in a cold storage house should circulate as little as possible from one chamber to another, in order that the odors of certain preserved products may not affect others. In particular, if the refrigeration of the cold store is accomplished

*Translated for the Smithsonian Institution's Annual Report from the Revue générale des Sciences pures et appliquées, Paris, twentieth year, No 5, March 15th 1909.

by means of air coolers it is absolutely necessary to have a special air cooler for each series of chambers designed to contain a particular product.

The articles to be preserved should not pass suddenly from the ordinary temperature to the temperature of the storage rooms, or vice versa, in other words, the refrigeration should be progressive. Thus in abattoirs the warm meat coming from the slaughter rooms is transported by means of an overhead rail into a cold anteroom kept at a temperature of 7 deg to 8 deg C There it undergoes for about twenty four hours a preliminary cooling at the termination of which it is carried into the rooms where the air is maintained at a temperature of 0 deg to 4 deg C and a humidity lower than 75 per cent Salting and treatment of the intestines the hides etc should be carried on in rooms entirely separate from the fore going which should be confined solely to the preservation of fresh meat

The question of the preservation of horticultural products is one of the most difficult in the application of cold to food stuffs The preservation of apples and pears has been studied in detail in the United States by Mr G H Powell He has placed results be fore the congress which demonstrate with the greatest clearness the effect of placing in the refrigerating chamber freshly picked fruits in comparison with those that have been exposed to the air several days after picking It is necessary to place the sound fruit in the cold fruit chamber soon after it is gath ered Other circumstances also influence its keeping qualities It is much better if the fruit comes from older trees It also appears that sandy soils are not favorable to preservation

Fruits with a thick skin keep much better than those with an easily ruptured covering The peach in particular is one of the most difficult of fruits to preserve M Loiseau horticulturalist at Montreuil however has succeeded in keeping this delicate fruit more than a month According to him it is especi ally necessary to maintain the temperature as con stant as possible varying not more than from 0 deg to 1 deg C

Among the recent applications of low temperatures which have been pointed out may be mentioned the use of artificial cold in the manufacture of paraffin and viscose

Crude petroleum generally contains from 5 to 6 per cent of paraffin in solution To obtain this paraf fin the petroleum is distilled until it contains from 10 to 25 per cent of paraffin Then by lowering the temperature of this liquid (paraffin oil) to a degree which varies according to the quality from +16 deg to —18 deg C paraffin is obtained which separates from the oil in the form of crystals which can be separated from the oil by filtration under pressure The application of refrigerating machines to this pur pose makes possible the treatment at one time of large quantities of petroleum As an example the works of Pardubitz in Bohemia are equipped with ma chines of a capacity of a million frigories and produce annually about four million (kilograms) of paraffin

The artificial silk called viscose is made by draw ing through very fine openings a thick solution of cellulose obtained with alkaline or sulpho-alkaline solvents (caustic soda and carbon disulphide) To accomplish this successfully the solution must be al lowed to stand in vessels cooled artificially to +2 deg C for a month or two before spinning The solution is then sufficiently pure to be decanted and spun with success

IV TRANSPORTATION WITH REFRIGERATION

The question of transportation of products under refrigerating conditions is one which has justly been a subject of careful consideration by transportation companies both on land and sea

The refrigerator cars or trains are of several types

(1) The refrigerator train consisting of a group of cars one of which has no capacity for storage but contains a complete refrigeration plant which feeds the other cars with which it is connected by suitable piping

The impossibility of breaking up such a train by uncoupling the cars from each other limits the practical application of these trains however except in a few instances This system was experimented with in 1905 in the transportation of Russian butter from Siberia (from Kourgane to Riga at a mean speed of 15 to 16 kilometers per hour) The cost of the re frigeration the temperature of the butter being main tained at a mean of 5 5 deg C was as high as 0 117 franc per kilogram of butter per day exclusive of the cost of the refrigerator plant

In this category must be classified the Russian re frigerator car of the Slitich system It is mounted on four sets of wheels on bogy trucks and is of the fol lowing dimensions Length 8 meters width 3 meters height 2 65 meters capacity 120 cubic meters It is divided into six compartments Two in the center contain the refrigerating apparatus while the other four may be charged with goods to be refrigerated

(2) The lack of elasticity of the refrigerator trains has been remedied by the use of refrigerator or in sulated cars The operation of these cars necessitates at the starting point an insulation composed of a re frigerating machine and an apparatus which forces a blast of cold air into the body of the car before and after charging When the interior temperature of the car has been reduced to the requisite degree the cold air is shut off and the car hermetically sealed In Springfield Mo there is an installation of this kind capable of cooling 40 cars of bananas at one time to 15 deg C

With this type of cars may be compared those where the low temperature is obtained by the previous cool ing of brine contained in coils about the roof o walls of the car The thermo regulator car of the Mak soutoff system belongs to this type The saline so lution which cools the air to about 5 deg C must be cooled every two days necessitating refrigerating sta tions every five or six hundred kilometers

(3) Besides the tributary cars of the refrigerator trains and those depending on an installation at the point of departure there are the self-cooling cars that is to say cars themselves containing cold produc ing agents These are the most universally used both in Europe and America

These may be divided into two great classes Cars cooled by ice and cars cooled by evaporation of a liquefied gas

In the ice-cooled cars the low temperature is ob tained by means of ice disposed in compartments along the roof as exemplified in the cars of the So ciété des Magasins et Transports frigorifiques de France or along the walls of the car as exemplified in the American cars and cars of the Moscow Kazan Railroad The plan of closing the body of the car completely from the outside air has been generally abandoned The ice cooled cars now in use are usu ally provided with an arrangement which draws in air from the outside and sends it after cooling it by contact with the ice to renew the air in the car The free space remaining for this disposition of the mer chandise is about 30 to 40 cubic feet allowing the in troduction of a load of from six to ten tons according to the nature of the products By an ice consumption of an average of 400 kilograms per day a temperature varying between 8 deg and 4 deg C is obtained The degree of humidity is high however

The cars cooled by evaporation of a liquid gas (in this case ammonia) carry on the outside two cylin drical tanks of liquid ammonia This fluid is sent by regulating cocks into coils placed at the two ends of the car on the inside The ammonia evaporates and absorbs heat the ammonia gas produced dissolving in water in a tank placed under the car One car of this variety was experimented with in 1905 in the transportation of butter from Siberia The cost of refrigeration for butter maintained at a temperature of from 4 deg to 5 deg C was as high as 0 068 franc per kilogram of butter per day

In the ice cooled cars of various types experimented with by the same Russian commission the total cost of refrigeration including all expenses (ice consump tion and charging installation of ice houses and op eration of cars) amounted to 0 009 franc per kilogram of butter

As the short summary I have just made shows the First International Congress of Refrigeration has ex amined with care most of the scientific and technical problems which exist in the refrigerating industry If it has solved any of these problems it has indicated in the form of resolutions a very great number of others which up to the present have been only incom pletely worked out The next international congress which will be held in Vienna in 1910 will not be in ferior to that at Paris and will bring us let it be hoped in the scientific phase to some accurate knowl edge of the properties of bodies at low temperatures and in the industrial phase to a uniformity of units of measure and methods of testing machines and in sulating material

Mica Production in India

By E Harran

India is at the present time the source of a little over half the world s supply of mica. During the five years 1904 to 1908 inclusive the quantity exported rose from 1 825 hundredweights to 41 256 hundred weights and the value from $415 915 to $1 237 680

Although a mica producing country itself the United States is India s best customer and of the total quan tity of mica produced in the Orient seventy five per cent goes to Great Britain which is the center of distribution for the States and Germany the latter country taking the next largest quantity after the former

The mica raised in India is the variety known as mucovite and is found in large pegmatite veins tra versing mica schists in various parts of the peninsula principally the east and south The two principal centers of production are the Nellore district in the Madras presidency and a tract of land about twelve miles broad and sixty miles long which stretches across the junction of the Gaya Hasaribagh and Monghyr districts in Bengal. In the latter of the two areas men tioned the mica industry is a very old-established one and can be traced back for several centuries In the former, however, the mining of the mineral was only started very recently, consequent on the discovery of rich deposits by prospectors employed by European capital. In this district the deposits occur in peg matite veins in granite, in micaceous gneiss in horn blende, and mica schists. The strata vary from a few inches to several hundred feet in thickness. These pegmatite veins (or "dikes" as they are sometimes called) consist of three essential minerals—quartz, felspar, and mica—in varying proportions In appearance they bear a resemblance to coarse granite, and the mica is usually found in those veins in which the constituent minerals have crystallised in large masses Where felspar and quartz are present in small masses the accompanying mica is usually of little value

The mica found adjacent to the surface is almost always soft and cracked quite useless for commercial purposes other than manufacture into the substance known as micanitte Clearer and better colored mica is reached lower down in the solid ground and as the tunnel reaches greater depths where the rock formation is harder and more uniform the mineral ex tracted improves in quality It is stated that in the United States no more than five per cent of the total yield of the mica mines is sheet mica In India how ever it is calculated that an average of ten per cent can be cut into plates the balance being either wasted or converted, in part into micanitte General experi ence shows that the mica mostly demanded from India by America is of the green and ruby colored varieties in sheets of three square inches and upward India actually produces the mineral in green, ruby, yellow white and amber colors These are divided into clear and spotted or stained varieties the clear ruby and clear green being the most valuable fetching as they do at present prices between $7,200 and $9 720 a ton Of the common varieties all sized sheets are readily obtainable at prices ranging from 18 cents a pound for 2 by 3 inches to $1 71 and 12 cents a pound for the larger sheets The presence of any metallic inser tions in the mineral renders it useless for insulating electrical purposes (for which the bulk of it is re quired) generally For these specific purposes the sheets must be flexible free from cracks capable of withstanding high pressure, and non-conducting. The Indian mines produce mica, conforming to this last specification, in large quantities.

The mica mines in Bengal are still worked in a very primitive way, in fact, in exactly the same method as they were worked centuries ago, when the principal use the mineral was put to was to fill the apertures of windows for which we now use glass The mica which generally occurs at the exposed outcrop on the hill face of a pegmatite vein is followed from book to book by underhand stopping which results in the production of holes some of which are now five hun dred feet deep The resultant material excavated con sisting of mica earth rock etc is brought to the surface by a string of native coolies being passed in cane baskets from one to another up rudely con structed bamboo ladders During the rainy season work is completely stopped for some three months say June July and August At other times when rain has occurred during the night the start of work in the morning is delayed for an hour or more while the resultant accummulation of water is being baled out by hand In Nellore and Mysore in South India min ing operations are carried out in a much more up-to date manner as a result of their more recent origin and the attention that European capitalists are direct ing to them

Dessau Gas for Balloons

It is but a short time since publicity was first given to the invention of a new method of producing a gas specially adapted for filling balloons The process was developed at the Deutsche Continental Gas Gesellschaft of Dessau and the name 'Dessau Gas has accordingly been applied to the product. A re port on some of the more recent developments in the new method is given by A Sander in Die Umschau The process consists in subjecting ordinary illuminat ing gas to a high temperature whereby the hydro carbons present are for the most part split up into hydrogen and carbon The reaction is one of that im portant class known to the chemist as 'contact ac tions that is to say it is greatly assisted by the presence of solid material offering a large surface to the heated gas

Accordingly in carrying out the process the gas

is led through retorts packed with small charcoal or coke (whose innumerable pores expose an immense surface to the gas) and heated to the proper temperature. The chemical change which takes place is accompanied by 20 per cent increase in volume. This together with the deposition of carbon which forms part of the change leads to a product very considerably lighter than the original illuminating gas. In fact its specific gravity, expressed on the basis of air as unity is about .2 to .3, whereas that of coal gas is between .4 and .5. The new gas therefore has considerably greater buoyancy or "lifting power" than ordinary coal gas. It contains about 80 to 84 per cent of hydrogen and 5 to 7 per cent methane, and is free from benzene and other hydrocarbons which attack the balloon cover. Its odor is rather more subdued than that of coal gas. The cost of converting illuminating gas into "Dessau" gas is quite low, hardly more than the cost of delivering the former under ordinary conditions from the works to the consumer.

Motor Truck for Hauling Building Stones

A New French Commercial Automobile

By the Paris Correspondent of the Scientific American

Of recent years automobile trucks have come into extensive use for hauling various heavy goods and we have seen an increasing number of cars placed on the market designed specifically for use in handling special classes of material.

Among cars of this kind we wish to illustrate one which has recently been built for handling heavy loads of cut stone for building purposes in Paris. The ordinary practice in such cases is to place the stone upon a timber rolling truck and draw it along the road. The car which is shown in our illustration is designed with special facilities for loading and unloading the truck with the greatest possible efficiency. In the form of truck used hitherto there was usually provided a swinging platform which could be let down to the ground and then drawn up with its load using a hand operated capstan for the purpose. To take a load of stone from the railroad depot or the quays of the Seine to the building site in the city used to require a team of five, six or more horses. The same load can be handled with an automobile truck at a much lower cost owing to the economy in wages, the elimination of the expenditure for maintenance of horses and the greatly increased hauling capacity per day. Another advantage which is well worth considering is the much smaller space which the conveyance occupies in the street, thus avoiding obstructions of the thoroughfare. These considerations have induced the association of building contractors and the Automobile Club to organize a prize contest for motor trucks. A set of rules were drawn up regulating the general design, dimensions, load, speed and other points. A road test was to be made outside the city over a thirty mile run without a load at ten miles an hour and a second test with the truck loaded with six tons or less, the cars being run in this case over a stated route within the city which included some steep inclines. The speed prescribed for this test was six miles an hour.

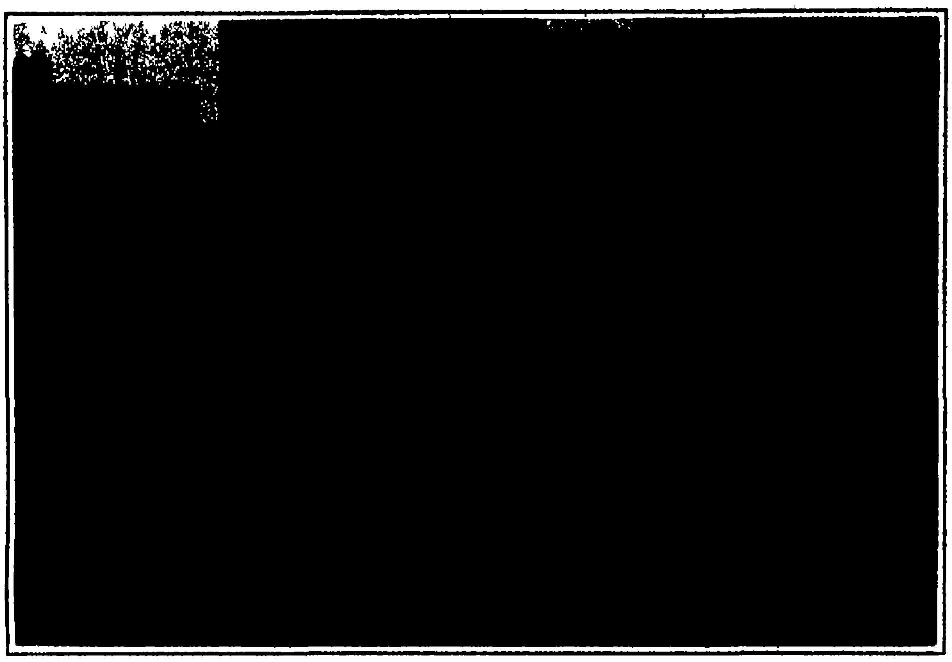
The motor truck described in these pages came out as the most successful competitor in this contest and received an award from the Commission. It is built by the well known French firm Creusot.

During the test just mentioned it carried a load of five tons representing an aggregate weight of nine tons over the route which included some grades of as much as 13 per cent, and gave complete satisfaction.

The spring wheels with which it is equipped give a very easy motion on the stone pavement.

This hauling car is made up of a main truck of the usual pattern for vehicles of this description to which is added a tipping platform that can be let down at the rear to discharge the load. Upon this tipping platform a roller truck travels which receives the load of stone or other material. On tipping the platform the truck rolls down of its own weight to the ground and is thus automatically unloaded. The platform is pivoted upon an axis located near the rear wheels of the automobile and some distance above the main axle. The pivot is mounted about the middle of the swinging frame but a little in advance of that point so that the platform when empty will automatically swing down at the back when its front end is released. The driver's seat is placed well forward and lies above the motor whereby space is economized and the total length of the car is reduced. Not counting the swinging frame the total length of the chassis is 15 feet 4 inches, the wheel base between front axle and rear axle is 11 feet. The wheels are of a new and special design and carry a set of broad steel tires placed over rubber rings extending between the tires and the hub. The diameter of the front wheels is 2 feet 10 inches and that of the rear wheels 3 feet 2 inches. The width of the tires is 4 inches in front and 7 inches at the back. The motor is of the four cylinder type with 5 inch stroke and 4 inch diameter. In normal working it gives 900 revolutions per minute and 30 horse-power. The fuel is either alcohol or gasoline, the tank being located under the driver's seat. The radiator is cooled by a blast of air thrown upon it by a fan and is located at the front of the car.

The tipping frame is built of longitudinal channel bars with a cross-stiffening of T irons. Along the side beams extends a T-iron which serves as a rail for the rolling truck carrying the load. In front these bars are curved upward to provide a buffer. An inspection of the drawing will show near the front end of the rolling truck two side plates perforated with round holes. These are provided to furnish a hold for inserting crowbars when loading and unloading. The platform, when loaded is held in place by a coupling link, which fastens it down upon the chassis at the front end.



THE CREUSOT MOTOR TRUCK. TAKING ON THE LOAD SECOND STEP

At one side of the chassis will be noticed the capstan which serves for loading and unloading. It is driven by bevel gears, one of these being placed in the circular space below the capstan and the second in the vertical gear case visible just in front of the same. On the shaft of the vertical gear is a sprocket wheel driven by a chain from the motor. To this end the second sprocket is mounted on one of the shafts of the speed-changing box of the car.

Underneath the capstan is a horizontal plate with projections which serve as a clutch to throw the capstan drum on or off the gear shaft. A ratchet and pawl serves as usual to prevent the capstan from slipping backward. A rope is wound around the capstan drum and is then coupled to the rolling truck, passing over a roller upon the tipping frame so that the load can be drawn up or else let down by the reverse movement. The operations of taking on the load or discharging it are easily carried out by using the present capstan device. To load the rolling truck with the stone upon the car, the swinging frame is tipped so that the rear end comes down upon the ground. Here the channel bars are cut off at an angle so as to give beveled ends in order that the truck may be readily rolled up. The cable is wound in a few turns upon the capstan and thence passes first around a sheave at the center and near the front of the chassis, and then down to be hooked to the front end of the roller truck. The capstan is thrown in gear by the lever of the clutch and the free end of the cable is drawn tight around the drum. As the capstan revolves the roller truck is drawn up, and when a certain point is reached the frame tips forward by the weight of the load and becomes lodged upon the chassis in a horizontal position. Continuing the operation, the roller truck is drawn to the forward end where its movement is limited by the buffers. It is held in this position by the link coupling which works as a guy coupler and is tightened down by a screw so that the truck is held firmly. The cable is [illegible] inches in diameter and a [illegible] load can be [illegible] at the rate of 1 foot per second. [illegible]

THE CREUSOT MOTOR-TRUCK. TAKING ON THE LOAD; FIRST STEP

to work with a heavier load than usual, say a weight of 6 tons, a pulley block is used with the cable so as to reduce the speed by one-half.

For the unloading operation, the capstan is made to draw the roller truck toward the rear of the tipping frame To this end a pulley is mounted at a point near the rear of the chassis, and the rope is wound around the capstan and passes from here to the rear pulley being then coupled at the rear end of the roller truck Working the capstan, therefore, gives the reverse of fect and draws the truck backward When it passes a certain point its weight causes the frame to tip down to the ground and the truck rolls down and off the frame To prevent the motion from becoming too sudden a braking action is given to the capstan by winding a few turns of a second rope on the free part above the main rope so that drawing upon it will slacken up the speed of the drum

The stone truck can be replaced by a box body adapted to hold any kind of material In this way the auto-truck can be kept in continuous service when there is no stone hauling to do. Commandant Ferrus, one of the members of the official commission con siders that this new car would be very useful in army work for quick transportation and handling of un mounted cannon

An Early Project for Wireless Telegraphy

It will probably be news to most readers that a wireless telegraph company was incorporated by act of Congress in the year 1873 The corporation was entitled the Loomis Aerial Telegraph Company and its members were Mahlon Loomis Alexander Elliott, and William N Chamberlain of Washington D C P R Ammidon of Boston and Isaiah Lukens of Delaware It was permitted to have a capital stock of \$200 000 and to increase the same to \$2 000 000 if the interest of the company should require

All that the act of incorporation tells of the purpose of the company is that the business and objects of said corporation shall be to develop and utilize the principles and powers of natural electricity to be used in telegraphing generating light, heat and motive power and otherwise make and operate any machinery run by electricity for any purpose"

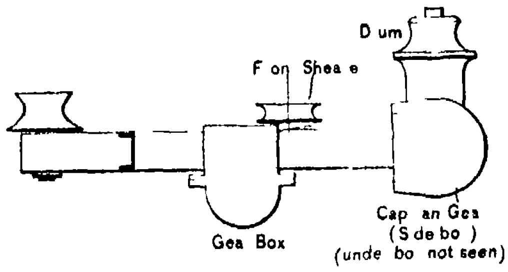
The Loomis Aerial Telegraph bill was introduced by Representative John A. Bingham of Ohio referred to the Committee on Commerce and thence favorably reported by Omar D Conger of Michigan on May 21st 1872 In Mr Conger's long and flowery speech the theory of the scheme was set forth as follows

"This theory assumes that the earth itself the atmosphere surrounding it and the infinite depth of space encompassing this aerial world contain a succession of concentric circles or planes of electricity of which those nearest the earth are perpetually disturbed by oceanic currents atmospheric changes alternations of day and night and the ever varying effects of solar radiation and lunar influences but that above these pierced perhaps by the tops of the loftiest mountains are concentric circles or vast sur rounding seas of undisturbed electricity which may be affected by any interpenetrating galvanic force from beneath causing electrical vibrations or waves to pass from that point within such electric plane around the world as upon the surface of some quiet lake one wave circlet follows another from the point of disturbance to the remotest shores So that from any other mountain top upon the globe any conductor which shall pierce this plane and receive the impression of such vibration may be connected with an indicator which will mark the length and duration of such vibration and indicate by any agreed system of notation convertible into human language the *messages* of the operator at the point of first disturbance and thus not only from one but many mountain tops piercing far above the circumambient atmosphere the devotee of science and the solemn student of nature may gather the unwritten messages of interest or affection from the silent solitudes of nature and the cerulean depths of heaven with unerring accuracy and transmit them to the denizens of all lands by the mundane machinery of telegraphic instrumentalities"

Mr Bingham more prosaically said I understand that the highest authorities on electricity both in America and Europe sustain the theory upon which this project is based to wit that the earth is negatively electric, and that the atmosphere above the earth is positively electric increasing in proportion as you ascend above the level of tide-water The project here proposed is simply to connect the air at a certain altitude (three or four miles if you please above the level of the sea) with the tide-water level of the earth by means of wires thereby completing the electric circuit."

Mr Bingham explained that the required altitude was to be reached by means of mountains that the company proposed "to utilize electricity wherever diffused through the earth and in the atmosphere of the earth for the purposes of light and heat and motion" (in addition to aerial telegraphy) and said that for three successive years he had introduced the bill and had it referred to the Committee on Commerce.

The principal opponent of the bill (Mr Charles W Willard of Vermont) objected to its passage on constitutional grounds, asserting that the power to incorporate belonged to the several States and that incorporation by Congress conferred an unfair advantage, and he was not moved from this position by the reminder that a telegraph company incorporated by Congress was actually operating wires from the Mississippi to the Pacific Most of the members of Congress, however appeared to regard the bill as some-



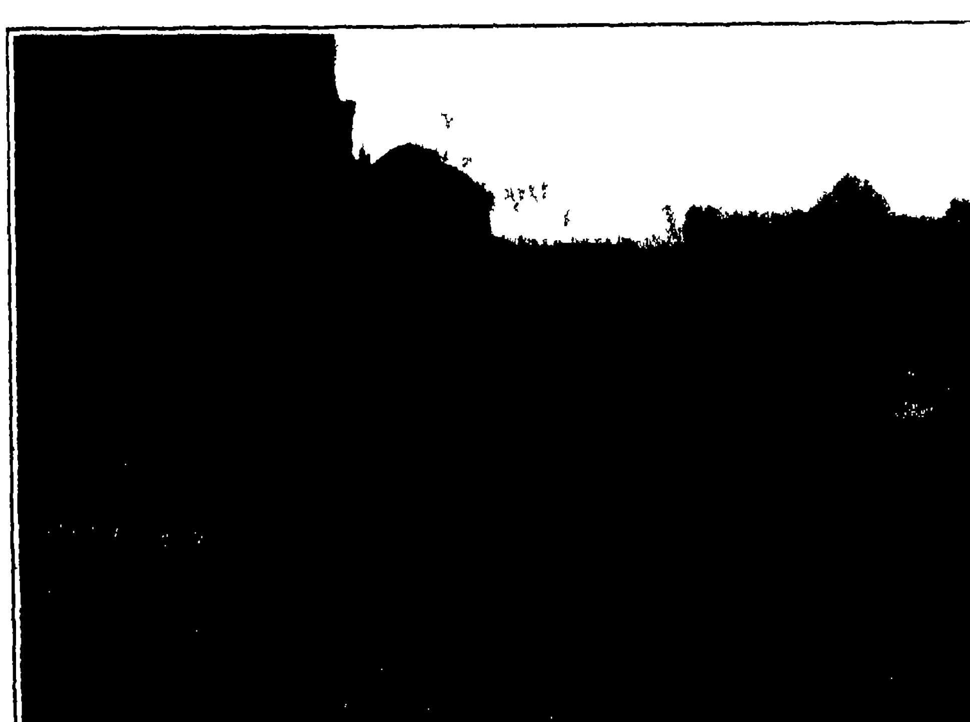
The Creusot Motor Truck—Details of the Capstan

thing of a joke and let it pass as harmless Yet this Congress the forty-second contained a distinguished array of men of great ability including in addition to those already mentioned James A Garfield (speaker *pro tempore* and subsequently President of the United States) James G Blaine (speaker) William P Frye Eugene Hale Benjamin F Butler Oakes Ames George F Hoar William H Barnum S S Cox Fernando Wood William A Wheeler (subsequently Vice-President) Samuel J Randall James B Beck Michael C Kerr Daniel W Voorhees Jeremiah M Rusk and others

On the day following the debate the New York *World* published a long editorial headed Airy Nothings filled with aggressive ridicule of the project and of "this electrical Conger whose name would lead one to suppose him a denizen rather of the water than of the air

This all happened thirty eight years ago How well may we learn at this time following the C Q D of the ill-starred Republic and the still more recent rescue of Wellman and his brave associates the value of some Airy Nothings of prophecy and the truth of Mr Conger's work Sir the visions of the seer are wont to be mistaken for the ravings of insanity The sublime revelations of prophecy as well as the announcement of important truths have oftentimes been deemed the vagaries of those whom much learning hath made mad

"This electrical Conger was the same man who urged the passage of the act which provid d funds and authority to send Gen Greely on his quest of



THE CREUSOT MOTOR TRUCK IN TRANSIT

the North Pole and in honor of whom Greely named Conger Inlet and Fort Conger celebrated as the abiding place of Greely and his men, and later of Peary and other Arctic explorers

A description of the actual conditions under which wireless telegraphy is commercially successful would differ little from the theory advanced in the debate on wireless telegraphy to which the House of Representatives listened "with dreamy indifference thirty-eight years ago

The Neglected Art of Mastication

The important part which chewing plays in nutrition is beginning to be recognized By thorough mastication the food is ground very fine and mixed intimately with saliva so that it is converted into a soft pulp which is then formed by the tongue into a bolus that is easily swallowed But the saliva the flow of which is increased by chewing has a more important f nction than lubrication It exerts a chemical action on the food converting its insoluble starchy co stituents into soluble sugars gluc se and maltose and the easily digested dextrin Mr Horace Fletcher has made himself famous by his advocacy of thoro gh masti cation and has raised chewing to a fine art He makes a study of flavors and hews his food ntil all its savor has been extracted and it glides down the throat spontaneously

With many of o r modern foods thoro gh mastication appears superfluous and we are apt to think it sufficient to cut the food into small pieces soften it with butter and sauces and wash it down with copious drafts of water and other beverages This artificial method is not an efficient substitute for the natural method of chewing and it produces decay of the teeth in addition to n merous digestive tro bles Teeth are or should be living tissues in which metabolism or renewal of s bstance is constantly going on If they are not used s fficiently they s ffer from mal n trition and lack of exercise and consequently decay With the decay of the teeth mastication becomes more imperfect and more neglected and th s the two evils poor teeth and poor chewing continually aggravate each other

Teeth need the exercise of chewing hard solid food Even children sho ld be allowed to eat the crust of bread and taught to chew this and other food thoroughly

The value of good teeth and the importance of a rational method of chewing wi l be demonstrated in vario s ways at the coming International Hygienic Exhibition in Dresden where it will be shown accord ing to *Hygieia*, the circular of the exposition that the action of the gastric juice is increased by thorough mastication of the food

A New Cement Compound

G ypri ith is a product patente l in Europe com posed of sand crushed stone and rapid setting Portland cement It is used for many purposes such as for facing upon almost any kind of material and especially upon concrete and it gives the appearance of stone The compound adheres strongly and can be easily washed No special tools are needed for p tting it on. Another use is for ornaments and these resemble stone s ch as relief work keystones capitals of columns etc Such ornaments can be made on the spot or produced beforehand and fastened in place when putting on the surface layer A reinforced concrete constr c tion treated in this way is said to present no difference from natural stone as to outside appearance and can be made as ornamental as desired being naturally much cheaper

The Reliability of Electric Furnaces

Factors in Their Development Under American Conditions

By F T Snyder

A few days since a man who had been in the East attending the meetings of an association of engineers representing an industry that uses a large amount of high grade steel in various forms was asked about the electric furnace paper on the programme He characterized it as the usual optimistic hopes by the agent of an electric furnace inventor But without the furnace inventors and without the optimistic hopes that held them for ten years to the expenditure of time and energy and money that was all outgo and results deferred there would be no commercial electric furnace work to-day to consider Moreover it now seems as though the time had come to point out to those who are less closely in touch than ourselves that the electric furnace has grown beyond a question of this or that inventor has grown beyond a question of hopes to one of commercial use and is now a matter of engineering and finance that to-day the electric furnace has achieved reliability

THE SIEMENS ELECTRIC FURNACE

But before the time goes by when particular arrangements of electric furnaces are named after their inventors as such time has gone by for the open hearth furnace and for the crucible furnace it would seem proper that we should call by the name of its inventor that simplest of all electric steel furnace in which a single electrode above leads the current through an arc to the steel and a metallic contact with the steel bath below leads the current back to the dynamo Back in 1880 so far back that the paper describing it was read before the Society of Telegraph Engineers then the only organization representing electrical engineering William Siemens built and operated his furnace in which the heat of the electric arc was used to melt steel This little furnace was a practical furnace It made good steel A duplicate of it copied from the old drawings will work to-day without difficulty making its little batch of steel It is especially fitting that to this same William Siemens the steel industry also owes its open hearth furnace only second in importance to the blast furnace itself

As the Siemens electric steel furnace was the first practical electric steel furnace so now it bids fair to be also the furnace to be used in the greatest numbers It is characteristic of the electric furnace that it is reliable in small units and it is in this direction that the industry is tending—the making of some steel castings by many of the gray iron foundries the making of their own steel castings by many of the larger users In these small installations the simplicity and reliability of the Siemens electric steel furnace will be important With proper engineering this single electrode type of steel furnace can be built reliably up to 500 kilowatts producing 250 tons of steel per month with continuous operation Many more than a majority of commercial installations will be below this tonnage A worthy use of this opportunity will be to emphasize the good to electro-chemistry that has lived beyond the life of this man by calling this type of electric furnace the Siemens furnace

COMMERCIAL RESULTS

Broadly reliability is commercial the ability to make a profitable return on an investment That the electric steel furnace is reliable in this way is emphasized by the growth of those plants in Europe that are making electric steel exclusively And beyond steel making the electric furnace has been commercially reliable so long in the aluminium industry that the general patents have run out The commercial reliability of the electric furnace in the manufacture of carbide has been for years in evidence with each user of acetylene light Less widely known but commercially profitable has been the electric furnace manufacture of carbon bisulphide of phosphorus, of graphite of abrasives of magnesium for flash lights of ferroalloys for steel refining and in the last few years we have seen the reliability of electric furnace operations pledged in the investments of the millions of dollars that are going into the construction of huge electric furnace plants for the production of fertilizers And it is the commercial reliability of these older electric furnace applications that is back of the reliability of the newer application of the electric furnace to steel In them was developed the demand that justified the building of electrode factories whose products are now available for steel furnaces In them was developed the special engineering ability to handle the large electric currents of furnace work They had their part in the demand for electric current at lower and lower cost It is these things that have given the Siemens electric steel furnace of thirty years ago a technical curiosity then, its standing to-day as a reliable industrial tool

Technically reliability is a matter of apparatus and men and supplies These react on each other Experienced and skilled men can force poor supplies and indifferent apparatus to a commercial output Apparatus that is inherently self regulating will permit the use of such men as can be had at a permissible cost Supplies that have a factor of safety in their constitution will carry the equipment through an over load Involved in the question of commercial reliability is the element of time Results must be prompt.

AN AMERICAN ELECTRIC STEEL INDUSTRY

To make electric steel in the United States means furnaces that are reliable with American men and American supplies In the rush of industry reliability cannot afford the time hazard of importation Europe developed the electric steel furnace industry first just as it developed the dynamo first, the steam turbine the large gas engine and steel making itself There the pressure of competition for opportunity the abundance of trained technical men and the low cost of capital force enterprise Safely we may look in America for the same swift overtaking of achievement with the electric steel furnace that has characterized other technical developments For this reliable American electric furnace supplies are now available and tested American electrodes can be had in sizes as large as furnace requirements call for Refractories made in this country have been developed with an ability to stand up well under the higher temperature of the electric teel furnace Campaigns with roofs of American brick have run into months as against weeks for European practice

Skilled electric furnacemen are scarce The rapid installation of furnaces more than absorbs the few who have had an opportunity to become experienced with electric furnaces working in commercial operation Trials with electric furnacemen imported have not been wholly satisfactory The drive of the American steel plant does not seem to fit with the methodical nature of the foreign technician This shortage of skilled furnacemen at permissible costs has thrown more of the burden on the apparatus has directed American electric steel furnace design toward inherent self regulation as we say electrically toward reliability as the investor looks at it toward making it fool proof as the man on the job phrases it Furnace detail that works very well in Europe with the skilled help available there has to be designed here to work with the help that can be had This inherent reliability can now be carried on to an extent that permits taking a steel melter from a crucible or open hearth furnace and putting him on an electric steel furnace with the assurance that within a week he can be making salable steel regularly This does not mean making an electrician of him Actually he knows no more of electricity than he knew of the kinetic theory of gases in his open hearth work but he does know that when the wattmeter needle is in a certain position he has a supply of heat in his furnace and hot heat at that and heat that, hot as it may be will not burn his steel

BETTER STEEL

But a reliable furnace and reliable supplies and reliable melters are not all of the commercial reliability of electric steel The steel produced is different from crucible steel It is different from open hearth steel If it were not different the electric furnace would not be used It is true that under favorable conditions steel can be made cheaper with an electric furnace than in other ways but the fundamental reason that is speeding electric furnace construction is that the steel is better Being better means differing chemically differing physically from the steels of the other furnaces and this difference chemically and physically must be reckoned with in the subsequent processes the steel goes through In the foundry the molding must be done for this new material It is freer from gases. It usually is hotter The tendency is to lower the carbon for the same tensile strength and this makes it set at a higher temperature. The improved elimination of phosphorus and sulphur tends in the same direction In the forge and rolls electric steel shows its additional strength and toughness

It must be handled from the point of view of its characteristics It is a mistake simply to consider the electric steel furnace as a substitute for some other kind of a melting furnace Its introduction can be counted on to mean changes of method as far as the steel is followed in manufacturing processes, and unless this is clearly recognized there will be disappointment and the reputation of the electric furnace for reliability will suffer

ELECTRIC FURNACE CONSTRUCTION NO EXPERIMENT

From a still narrower technical point of view, reliability means freedom from actual breakdown, from the enforced necessity of change in construction and the consequent loss of time and productive capacity As to this, electric furnace design is now on an engineering basis Dependence on experiment is now a matter of volition on the part of the investor It is no longer a necessity As a piece of engineering apparatus an electric furnace can now be more closely designed to meet narrow specified operating conditions than can an open hearth furnace

In a recent instance an electric furnace and a small open hearth were installed side by side in a new steel casting shop The open hearth gave trouble and has been replaced by a better design. The electric furnace although not of most modern design has operated without need of alteration Those details in which an electric furnace differs from established open hearth practice—the electrode holders, the electric regulation the contacts with the bath of steel—are now rugged and simple Electrode holders are in evidence that operate with less than one hour's lost time in a hundred beats

THE RECORD OF A WESTERN PLANT

Recently I have had occasion to examine carefully in detail the condition of a plant using electric furnaces exclusively that started operation on a commercial scale in the summer of 1907 and that is quite aged as electric furnace design goes It is proposed to double the size of the unit and increase the size of this plant fivefold and this examination was made to determine from the condition of the plant and the operating history what changes in the original design could be made to advantage in the extensions Incidentally the examination disclosed a condition of continuing reliability that is worth recording Substantially all of the original equipment was still in use The plant which is in the West has been operated since its installation by Chinese labor under a white superintendent, and neither the superintendent nor the Chinamen knew more of electricity than is involved in the opening and closing of circuit breakers and the reading of ammeters and voltmeters One of the power transformers had been replaced but it was learned after its removal that the trouble was an abraded spot on a terminal that could have been readily repaired on a Sunday at the plant. This particular plant while not a steel plant, is of interest in showing on many of its operating records a heat development efficiency of over 90 per cent—that is of the heat equivalent of the energy delivered to the plant by the high potential electric wires, over 90 per cent is transferred to the material under treatment

CHEAP ELECTRICITY A PRIME FACTOR

It is to be expected that the success of this new and flexible tool of industry will lead to over enthusiasm and to its application in wrong ways and in wrong places and that its failure as a panacea for troubles it has properly nothing to do with will bring setbacks But back of its present success is the cause of that success the steadily lowering cost of electric currrent Thirty years ago the furnace of Siemens worked as an apparatus It was not until the cost of current dropped below the figure at which the electric furnace was commercially reliable in this country that its industrial application began and its engineering side developed This dropping of the cost of electricity is still going on and as it goes on it brings a greater and greater motive force to bear on the installation of electric furnaces At the same time unfortunately for industry in general but fortunately for the electric furnace the cost of fuel for direct and gaseous heat is slowly but steadily rising.

Summed up more briefly the facts that an investigator of electric furnace results may expect to find are

1 That the electric furnace itself has passed from the field of experiment to that of engineering but that the fields of manufacture using the electric furnace products are still experimental

2 That the electric furnace is technically reliable and will operate continuously with the men and supplies that are available in this country That the details are simple and rugged, and that the inherent regulating powers can be made such as to bring it well within the ability of usual plant labor

3 That the electric furnace is commercially reliable That when installed with the same business care and adaptation to conditions that should be used with other furnaces, it will earn a profit on the investment, and a profit that is larger than the normal manufacturing profit in proportion as the field is more open

A paper read before the Chicago Section of the American Electrochemical Society

Art and the Engineer*

Combining the Useful With the Beautiful

By James P Haney

A SHORT time since New York city made a very extensive showing of charts and figures to explain to her citizens how she spent their money One room of this Budget Exhibit was given over to the work of the Municipal Art Commission Here were hung upon the walls a number of plans some of modest projects—a park fence a street lamp or fountain others of large and costly structure a memorial bridge a municipal ferry house a mile of river piers These plans were all in pairs and on one of every pair was stamped the word "rejected" on the other "accepted" These terse commentaries meant that the Art Commission whose business it is to pass upon every city building picture statue or engineering work had thrown out certain plans because of their artistic shortcomings Here was a very practical lesson on the value of art addressed particularly to the engineer

To the man trained in shop or laboratory the word "art" implies a rather hazy and indefinite something which has to do with the painting of pictures and the making of statues In a lesser way it is felt to be associated with the concoction of prettiness and the decoration of bonnets dresses and other feminine gear That on the contrary it is a very vital and practical thing underlying the successful development of huge commercial enterprises is an idea not grasped

Yet, in the exhibition to which reference has been made art appeared as an element which in one case led to an accepted plan and a busy firm and in the other to a rejected design and an idle office In neither case did the decision depend upon the engineering knowledge involved The shortcomings were not structural but artistic Two plans of equal merit from an engineering point of view were not of equal value in the eyes of the commissioners It was their business to select the project which was better in design—that is better in artistic relations To understand something of these relations and how they are created must then be important in the training of one who is later to play the part of a creator and builder of structures large and small

The development of city art commissions is only a new expression of a very old desire It is the effort of a town's people to secure beauty in their surroundings and this search for beauty is as old as man Of all human instincts there is none deeper than that which leads man to adorn the things he possesses to decorate his person his tools and all his belongings This desire says Carlyle is the first spiritual longing of the barbarian The savage who dwelt in the dim dawn of history has left us no trace by which we can know him save the drawings with which he decorated his stone cave His successors as they have struggled upward through the ages have in turn left results of similar desire to beautify things in jewels in carvings in temples and in tombs

Art has thus meant many things to many men but after all can be best defined as the search for beauty and beauty is something which does not lie without but within us It is our own response to that which stirs us it is a personal thrill and is in us and not in the thing which moves us Herein is art's great secret we can know no beauty that we do not feel Art is dependent upon appreciation born of an emotion To make such appreciation sensitive to fine forms beautiful lines and harmonies of color its lessons must be taught early in the life of the worker It is not a thing that can be gained in a few lessons or lectures as a minor part of some complex curriculum It is something which must be secured through an effort actually to create fine forms—an effort extended over a series of years through which the student has by criticism and comparison of his work with that of master craftsmen learned to refine his taste and to respond—to thrill—to harmonies ever more and more subtle

One who is to learn what art is must come to understand as his first lesson that it is not something apart and unrelated to him something to be raised by others for him to admire Rather it is that which he can create himself indeed something which he must create himself even in the simplest business of his life The decoration of a room the hanging of pictures on a wall the choice of colors in clothes and furnishings, all are of everyday experience yet they call for just the knowledge of what makes for beauty in line and form. And this same knowledge is daily required throughout the business world No office can be equipped, no advertising matter printed no lofts arranged for the sale of goods or windows devised for their display without appeal to these same principles

To learn thus, that art is common is not to learn that it is commonplace There is a luxury of taste which far surpasses the luxury of wealth The latter cannot by extravagant expenditure secure the results which are attainable by practice in choosing between things esthetically good and bad Choose however we must every day and many times a day and each choice is a matter of judgment Such judgment is born of discrimination We call it taste To realize this is to realize that we are all designers and that we must make pattern every time we dress ourselves equip an office or as engineers or architects plan the simplest of constructed forms

Art thus seen is plainly no unnecessary extra to be tacked upon the course which the engineer studies but a very practical subject which rightly taught, will color his judgment and give him breadth and insight far beyond his unschooled fellows It is something which deals with design both constructive and applied Its principles are those which underlie all good arrangement fitness to purpose proportion unity and harmony The laws of design based on these principles apply just as truly and surely to the planning of a bridge of mighty span as to the pattern of a door handle or a gas fixture They apply just as surely to forms we deem unimportant—the factory stack or the gutter curb as to the monuments and parkways which are a city's pride

Not until the student has grasped these principles of design does he come to realize how far the engineer controls his audience how far in others words one who understands movement balance and rhythm of lines and masses masters the eye of the observer and makes it look where he will It is this knowledge which guides the architect in his arrangement the sculptor in his grouping the painter in his composition With it Le Page in his Joan of Arc by a score of subtle devices fastens our gaze upon the face of the warrior maid We can look away but for a moment and in a trice some branch or shaft of light or shadow brings us again to the focus of the picture—to the eyes filled with the divine vision

Design may thus work miracles It can dignify the plainest of work by elegance of form and proportion It can ennoble the simplest of materials in structures fine in mass and color It is within its power to make that which is light seem strong and substantial to make that which is heavy yet seem instinct of a joyous and dynamic spirit The latter is the power which resides in the mighty cathedral of Beauvais whose huge piers lose the crushing sense of weight and break into columns which spring between the painted windows and draw the eye up past the lights of the clerestory into the shadows above where dim pictures of angels and saints hint of a heaven higher still

Art it has been said has meant many things to many men The student of shop and laboratory who would learn something of its stimulus and power must not be content then to look only at the work of engineers or architects Man has an inheritance of which great buildings monuments roads and aqueducts are only a part For centuries art has permeated the life of every country Our understanding of the past—of the Egyptians the Greeks the Romans and the Teutons all who lived around the Mediterranean and the Baltic and all of whose dynasties rose and fell in the mysterious East—has been gotten from their search for beauty The work of long-dead artists now fills our museums and forms our artistic legacy It is art's contributions from the past to the work of the artisan of to-day

This art heritage is to be read in the treasures of a host of kingdoms whose artisans in metal and in ivory in clay in glass in silk have dignified craft work and made it precious through their search for beauty in its working Every material which could be woven, tempered spun chased or tooled has had in art's history the lifelong study of many master craftsmen The very difficulties of its working have been made the pleasure of minds that delighted to find new ways in which it might be made to serve art's purposes To understand this heritage—to read it aright—is to gain a sympathy with those who through a hundred generations have made art the sovereign mistress of their daily work and have served her with lifelong devotion

Out of this wonderful legacy there stands forth for the engineer structures willed to him as a special inheritance These may well serve to thrill his heart and stimulate his admiration for his forbears and their work For him the pyramids temples and obelisks spell a lesson which the untaught may not read the Acropolis stands as a chapter printed in gold and all the seven hills of Rome as a great volume written by artist engineers. For him the great churches of France and Italy of Spain and England and the Low Lands speak the patient working out of trying problems in the hard school of experience the long dykes of Holland tell of the will and skill of a wise and courageous people the great châteaus of France of men happy in their power of wedding use and beauty Through these lessons he can learn to read the devotion the toil the aspirations triumphs and failures of those who have gone before As the heir of the ages he now of age himself may enter into his own

There is another lesson for the student who studies the structures of the past As the work of men long gone now teaches him so he must remember that he will play the part of teacher to those who are to follow Just as he is designer despite himself so of necessity he must become instructor to all who are to see his creations He may design well or ill and so be a helpful teacher or a vicious one But teach he must the very size and publicity of his work make it impossible for him to escape If it be beautiful it will impress its lesson upon every member of the community As fine monument well proportioned building gracefully springing viaduct or soaring tower it will subtly and surely increase the pleasure of all who see it If it be ugly and ill adjusted to its surroundings squat and heavy in its form or weakly decked forth with small and busy ornament it will help debase the taste of all who know it

The young engineer dreams of some great project which may later be delivered to his hands—some huge bridge some great terminal building a dominating tower or a stately church Art warns him that if his dream come true it will be his to create that which may either be a delight to all who see it or something which because of ugliness will be a blight upon the city The bad picture we may hide the ugly park we may replan but the structure of steel or stone or brick or concrete remains to hearten or to haunt us

Art then is at once a personal asset of its possessors and an immense civil and national asset when expressed in the work of the engineer Thousands go abroad to see fascinating cities reared by the labor of artist and artisan These cities profit in no small measure because of the beauty which their architects and engineers have created Their people delight to show the stranger what knowledge and affection have done to dignify great markets highways parks and avenues There is both an economic and a civic moral in this And of the two the civic is the more significant The engineer whose work is to find place even among the crowded tenements can yet help by his building to add to the pride of those who rejoice that they are citizens of no mean city Of this pride is born a keener feeling in her welfare a more loyal devotion to her interests and a quicker sensitiveness to all that does her ill

Yet another quickening force appears in the relation of art to the engineer In all things is a duality We live as well in a world spiritual as in a world material Not only esthetic lessons but spiritual ideas breathe forth from the work of one inspired by art Thus in the hands of the engineer art in the past has preached many sermons Every religion has called upon it for aid and every faith has seen its hopes made visible in temple shaft and aspiring pinnacle Strength sobriety sublimity are ideas as well to be expressed in steel or stone as in the spoken word

Through the spiritual insight which Art gives the beauties of Nature are to be read in a new language Her moods of pearly dawn of gray and rolling cloud of mystery of night and splendor of the storm are for those whose sense has wakened to the thousand lines and hues in which she paints her patterns and in which she tells the story of the living world The fascination of this its endless variety are first for those who through art's training have learned to look upon Nature with sympathetic eye—with the painter's vision—which sees beauty in the foggy dripping wood land and stunning force in the heave and thrust of a huge shoulder of a wave drawing past a headland in the sea

These things of the spirit once felt cannot but enter into a man's work be it never so simple and never so confined If he feels them they will speak for one can but talk the language of his mind If one thinks small thoughts his work will surely be mean and cramped If he responds to man's noblest efforts and to Nature's noblest teaching his creations cannot but reflect this inspiration Art for the engineer as for painter sculptor or architect for craftsman writer or musician is the talisman the spell which sets the spirit free Through it the worker may learn that which for ages has been the keenest spur to labor—the delight in service which seeks to praise God through one's craft

* A lecture delivered before the Stevens Engineering Society

Modern Coal Cutting Machinery and Mine Railways

Remarkable Labor-Saving Devices

By Frank C Perkins

MODERN coal mines are now equipped with many most remarkable labor saving devices operated electrically and by compressed air including coal cutting machines p n hers and mine haulage engines The d tails of construction of the electrical equip n nt a d con rol of mining locomotives as utilized in modern pr tice are of special interest Various types of su h lo omotiv s are in use differing more or less in ap arance and structure A good general view of two exampl s is shown in Figs 1 and 2 of our illustrations The former represents a 10 ton electric lo omotive delivering bituminous coal out of the rooms of th mine of the Hitchman Coal an l Coke C mpany

In the view reprod ced i Fig 2 a 12 ton Jeffrey lo omotive is seen delivering a train load of coal from the mines of the St Bernard Coal Company to the tipple In very low mines and where b it a few cars are handled six ton locomotives are frequently employed while for heavy service in the haulage of long trains of heavily loaded cars large locomotives of 16 tons are us l At the mines of the Westmoreland Coal Company where extra heavy service is required the locomotives reach a figure of 30 tons They are eq ipped with three motors whose electrical connections are indicated in the accompanying drawing Fig 3

The series wound electric motors are electrically connected so that the same current passes through the armature windings and through the field windings A flexible cable conducts the current from the trolley harp to a fuse or circuit breaker as a protective device inclosed non arcing fuses being usually employed with a lightning arrester connected between the trolley harp and the fuse when the mining locomotives are operated outside of the mines to any great extent or distance

From the protective device the electric current is conducted to the controller the electrical connections of which are indicated in the accompanying drawing (Fig 3) The controller includes a cylindrical switch for throwing resistance into and out of the motor circuit and also a reversing switch for changing the direction of the current through the field of the motor and the armatures in order to reverse the direction of travel of the locomotive

Usually a series-parallel switch is arranged in connection with the reverse switch so that the motors may be connected either in parallel or in series as desired

When the power house is located at considerable distance from parts of the mine the line loss is often so great in distant sections that the motors when connected in series will not receive enough current to start heavy trips and in fact with motors connected in series it is possible for one of the motors to start to slip its wheels before the other motors start The explanation of this is that as soon as one of the motors starts to slip its wheels it sets up a counter electromotive force which reduces the current flowing and the result is the other motor does not get sufficient current to develop any great effort, consequently the loads cannot be started With motors connected in parallel each motor takes current independently of the other and each exerts its full effort.

The operation of the controller is as follows The first resistance contact which comes under its brush permits current to flow through all of the sections of resistance coils in series thence through the motors to the rail or in case of a double trolley system to the other trolley wire The second resistance contact coming under its brush bridges the first section of resistance The third resistance contact coming under its brush bridges the first and the second section of resistance and so on until all the sections of resistance are bridged and the full electromotive force of the line is applied directly to the motor terminals From the resistance at the controller the current flows to the reversing and series-parallel switch This switch usually consists of a wooden cylinder inside of the controller case to which are fitted copper segments engaging with the contact brushes which are the terminals of the motor leads

Electric power is held by many mining engineers

MODERN COAL-CUTTING MACHINERY AND MINE RAILWAYS

the most economical and satisfactory power for heavy service coal cutting in modern mines, and it may be of interest to consider the method of operation of these labor-saving devices as utilized in a mine of the new Pittsburg Coal Company. The accompanying illustration (Fig. 4) shows a heavy electric coal cutter of the Jeffrey type in the operation of starting a cut in this mine. In the design and construction of such electric coal cutting machines all parts are made interchangeable to insure quick repair as the machines are required to withstand very rough work and the abuse incidental to mine service.

The cutter chains must be of great strength in order to resist the sudden and excessive strains and the wearing parts must be specially proportioned to insure the longest life possible while the electric equipments are required to have ample power to withstand the most severe work with great overload capacity.

The openings in the chain links are arranged at such angles that either chisel or straight pick pointed bits or combinations of both may be used according to the character of the cutting.

As the depth of the under cut should always approximate the thickness of the vein the lengths of the cutter frames are usually 5, 6 and 7 feet while the width of the cutter head for breast machine is generally about 44 inches. In some instances a 39 inch cutter head is utilized where the cuting is hard or when for any other reason a narrow head is preferable. With these electric coal cutters the speeds of the feed and pull back can be varied to obtain the largest output consistent with the hardness of the cutting and for this class of service electric power is in almost universal use being economical in operation and effective in working allowing a great output for the amount of energy expended and the time labor and money invested.

Air power coal cutters are extensively used in the mine of the Westmoreland Coal Company. A machine of this kind is displayed in Fig. 6 at the mine entrance. It is mounted on a steel truck so designed that the cutter may be loaded and unloaded with minimum effort and loss of time. In Fig. 5 an air power cutter of the Jeffrey type is shown just starting the last cut at the right hand rib in the Westmoreland mine. It is of interest to note that this machine was designed for use in mines where ventilation is a perplexing problem owing to gas and dust and also in mines where compressed air plants had been installed prior to the application of electricity for underground use. The solid build and resistance to wear of this machine have caused its adoption for a large number of mines where the cutting is hard and being of the chain type it makes less fine coal and less dust than other air machines in service. Pneumatic coal cutters similar to those shown in the accompanying illustration have been operated to special advantage at the mines of the Massillon Coal Company and also in a rather different class of work for cutting cement limestone in the mine of the York Portland Cement Co.

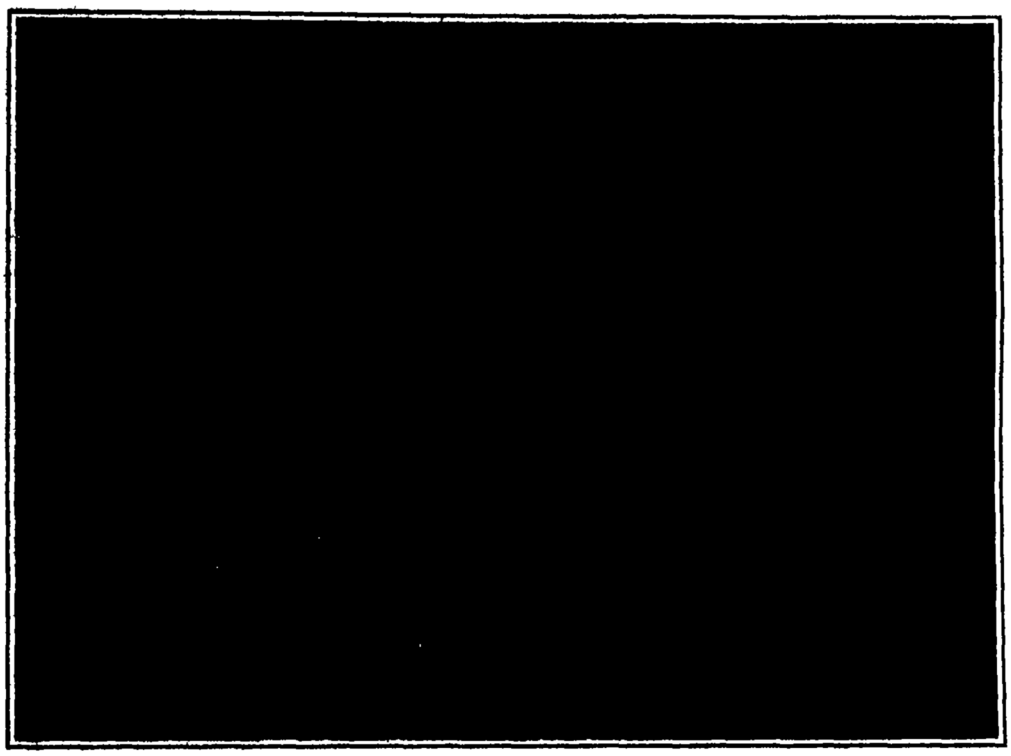

FIG. 6.—PNEUMATIC COAL CUTTER.

The early machine coal cutters driven by compressed air were of the cutter bar type as distinct from the chain type now commonly used and had cylinders set vertically on the frames or carriages. There have been modifications and improvements made from year to year for the last four decades as the demand for the machines increased, and new conditions in mining developed until the form illustrated known as the air chain mining machine was evolved. There are to-day only two distanct types of air coal cutters in use, one commonly known as the puncher and the other that mentioned in the foregoing.

It is generally conceded that there are in the United States certain mining districts where the "puncher" machine can be used to greater advantage than the chain or breast type and this occurs where poor roofs necessitate propping very close to the face or where rolls are met with in the mine and the coal is frequently cut out or in mines where an excessive amount of sulphur in the form of sulphur balls occurs in the bottom of the veins where the cuting is to be done. In the majority of mines however where the conditions of mining are normal chain or breast type of machines can be more advantageously and economically used than the puncher.

Pneumatic mining machines are designed for five six or seven foot undercuts and for seams under five feet in thickness. The five foot undercut is commonly employed while for seam ranges from five to six feet the undercut generally desirable is six feet and for thicker seams seven feet.

In this construction the cutter head can be either thirty nine or forty four inches wide and for all ordinary cutting the forty four inch cutter head is used but when the cut is extremely heavy the thirty nine inch head is preferable. Either chisel or pick point bits or a combination of both can be used to suit the character of the coal to be cut and various speeds of feed and pull back are arranged to suit local conditions. The machines are provided with the necessary jacks to hold them in position and with trucks adapted to the track gage. For the air hose about fifty feet of one and one half inch wire wound pipe with couplings is commonly employed.

The air machines have of course a special advantage in places where air power is already installed as they can be put into operation without changes in power equipment or pipe line.

While compressed air puncher machines are used extensively in mines in many instances electric power only is available. In such cases the so-called pneumatic electric puncher is operated with great economy. This mining machine which is shown in operation in Figs. 7 and 8 consumed only 7½ horse power whereas machines of older design and construction having an equal cutting capacity require from 20 to 30 horse-power.

While the application of the electric motor for driving the chain machine was comparatively simple for the rotative motion of the motor readily lent itself to driving the chain through the medium of gears the problem of adapting a motor to give reciprocating motion to a pick was far more difficult of solution.

In a percussive tool the vibrations if transmitted directly would be more or less destructive to the electric motor and while the problem has been considered from almost every conceivable point and upon every conceivable basis experience has practically demonstrated that in order to give sufficient flexibility the blow itself is best struck through the medium of compressed air. In the electrically driven puncher a compressor cylinder is used and unique means of compressing the air have been devised.

The driving motor is of the ordinary series wound four pole type. The shaft of the motor is vertical

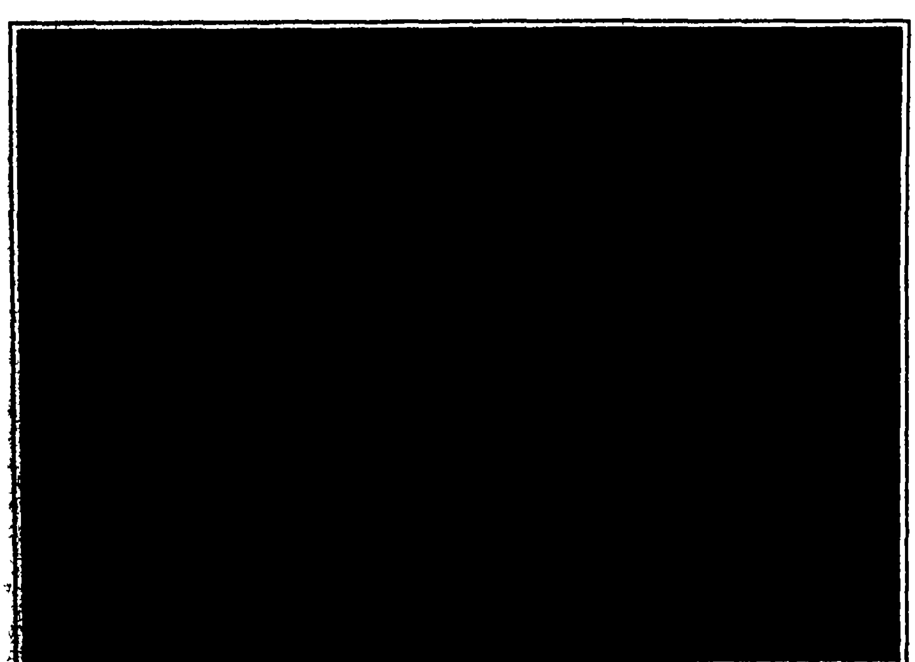

FIG. 7.—A PNEUMATIC ELECTRIC PUNCHER. VIEW SHOWING BIT.

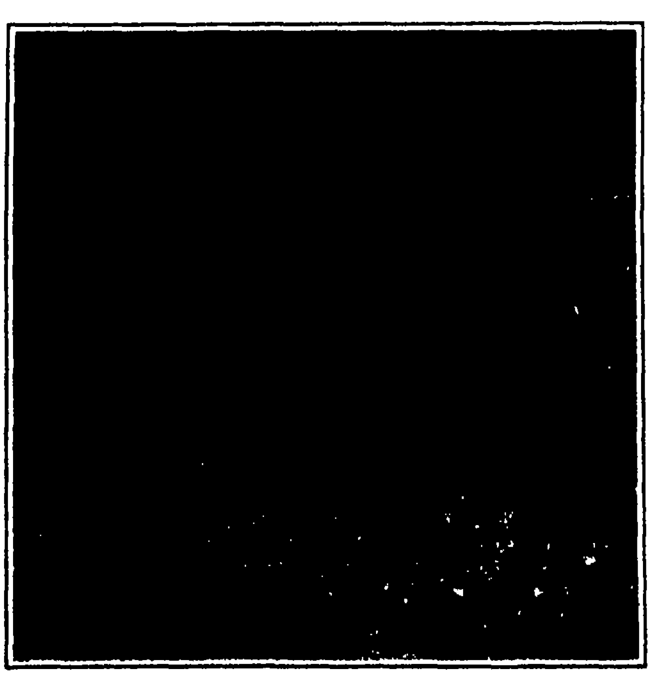

FIG. 8.—A PNEUMATIC ELECTRIC PUNCHER. REAR VIEW.

MODERN COAL-CUTTING MACHINERY AND MINE RAILWAYS

and the latter is completely inclosed, the frame and gear case cover being made in one piece of cast steel giving strength minimum weight, and simplicity

The support of the upper or commutator end of the motor shaft is furnished by a radial ball bearing while at the lower end is provided a ball thrust bearing to take up the weight of the armature and also a long bronze bushed bearing to take up the lateral thrust due to the motor drive

On account of the necessity of employing an inclosed motor the question of ventilation and cooling of the various parts became an all important matter It is accomplished by the very simple expedient of drawing the air to be compressed in through the armature and field windings at each forward stroke of the air compressing piston By this means about 28 cubic feet of cool air per minute passes over the heated parts at a velocity of about 2½ feet per second This method has been found very effective and is at the same time entirely automatic requiring no auxiliary appliances

The circular motion of the motor is by a novel and peculiarly simple arrangement of gears transformed into the straight line motion of the primary or air compressing piston located in a cylinder at the forward part of the machine. In the same cylinder is a second piston, connected with the striking pick, but having no mechanical connection with the first. Under the influence of the air which is compressed by the first piston and delivered through the open ports controlled by the same piston the second piston is alternately driven backward and forward but always prevented by the air cushion from striking at either end of the stroke

The extent to which the pneum-electric machine has been introduced has fully demonstrated its usefulness under all conditions of mining In hard or soft coal thick or thin veins, bad or good roof rolling or level bottom and narrow or wide work it has made records which place it at the front and its performance under these variable conditions has been such that it can justly be classed as a machine entitled to consideration as one of the most important factors in mining equipment.

The thrust due to the weight of the large reducing gear and its shaft, is taken up as in the case of the armature upon a ball bearing and the lateral thrust is resisted by a long bronze bearing which extends the entire length of the reducing gear shaft

The electric pneumatic puncher as noted in the illustration, Fig. 7, is provided with a reel and cable, the latter being used for conducting the power from the main and cross entries to the face of the coal. The cable is wound on the reel in such a way that connection can be made to the machine and entry wires, without unwinding more than sufficient cable to reach from the entry to within a short distance of the machine From this point the power is conducted to the machine, by means of a short cable varying in length from 30 to 50 feet. The long cable is of the twin type, the same as commonly used about mines in connection with other electrical machinery, except that it is unusually well protected from danger of injury by the hard service which it is required to withstand

It will be seen that this equipment is a great convenience as by using this cable it becomes unnecessary to carry wires to the face of the coal in the entries and narrow work. Piping, which is required in connection with air machines, is avoided, and the only permanent lines for transmitting the power are the copper wires which are strung in the main and cross entries. The same wires are also used for furnishing power to haulage locomotives, pumps, drills coal cutting machines etc.

Environment and Heredity

Modern Studies in Experimental Evolution

By Dr D T MacDougal, Ph D, LL D

Desert Laboratory Carnegie Institution of Washington

It is unanimously agreed that organisms plants as well as animals change individually in aspect in form and structure of organs in function and habit as they encounter swamps saline areas gravelly uplands or slopes climatic differences identifiable with latitude or elevation and other physical and biological factors It is generally assumed that these somatic alterations are accommodative and adaptive making *the organism more suitable for the conditions* which produce the changes Such an assumption is an over reaching one Any analysis of the changes which an organism undergoes after transportation to a new habitat will disclose one of a few alterations which might be of advantage in dealing with the newly encountered conditions but with these are many others direct necessitous atrophic or hypertrophic as to organs which have no relation whatever to usefulness or *fitness* Further a critical *examination* fails to disclose any theoretical considerations or any actual facts which would connect inevitably the somatic response with the nature of the excitation outside of the specialized tropisms in which specific reactions are displayed Even in these the adjustment is of such nature that a mechanism specially perceptive to contact for example may react to changes in temperature as illustrated by tendrils and many similar cases might be cited *It is evident that the soma of a* plant or animals is not to be considered as capable of adaptive alterations to every new agency which may cause changes in its form structure or function ation

Recent events in the field of evolution comprehend a number of movements and accomplishments of extraordinary interest The rediscovery of the facts of alternative inheritance the formulation of the concepts of equivalent balanced paired or differential characters the results of statistical studies of variability the analysis of species of various constitution by pedigree cultures in which the value of fertilization from various sources is carefully measured the distinction of the biotype or genotype as an hereditary entity the possibilities in the action of pure lines within a specific group the cytological contributions of fact and forecast upon the physical aspects of heredity and lastly the presentation of the facts and allowable generalizations identified with the mutation theory comprise series of advances of accretions to knowledge furnish a broadened foundation for biological science and disclose additional possibilities in all lines of experimental research with living things beside opening up new realms for speculative thought and stimulating the scientific imagination to renewed fruitfulness Nothing in the whole field of biological research surpasses in importance the problems as to inheritance of environic effects or as generally stated 'the heredity of acquired characters a subject which enlists additional attention from its specific sociological bearing

Among the most noteworthy investigations of environmental effects are those being made by the anthropologist in which somatic calibrations of immigrating races and linguistic studies of peoples of known origin geographical movement, and established relationship are being used to great advantage No more fascinating chapters of scientific literature are to be found than those which delineate the migratory movements segregations and habitual reactions of Polynesian islanders of North American Indians or of Asiatic peoples yet their value as actual contributions to biology is hardly recognized The investigator of problems in anthropology has the advantage of dealing with an animal whose psychology history traditions and records are readily intelligible to him so that a much wider range of facts may be brought within the zone of reliability than when we deal with an organism whose actions are but imperfectly understood

If a general view be taken of the available information of interest in this connection three classes of facts will be discerned One group is comprised in the mass of information obtained by the operations of the horticulturist the agriculturist and the breeder as to the behavior of crops plants and domestic animals when *transferred from one habitat to an* other The greater part of such data is the result of observations which do not comply with the ordinary requirements in the avoidance of error so that strict comparisons as to the behavior of organisms under the conditions of various habitats are impossible A consideration of the literature yields many suggestions for experimental research and the simple generalization that the direct effects of climatic complexes *on the seasonal cycle* and upon *color or structural fea*tures of the individual may be repeated or carried over two or three generations in a habitat where the specific casual combinations are lacking This is the available total of knowledge furnished us by economic operations and by the introduction operation of botanical gardens and plantations

A survey of the activities of the biological laboratories of the world during the last five years reveals the fact that an enormous amount of attention is being paid to the subject and that already results of very great importance to the student of evolution have been secured The nature of these contributions and the increase of information accruing from them may be best illustrated by a citation of some of the more notable experiments

Pringsheim after a comprehensive review of his own work and of other available evidence obtained by a study of accommodations or adaptations of yeast and bacteria to unusual temperatures culture media, and poisons concludes that some of these variations are fixed and transmissible both asexually and by spores while others are not There are a number of records of the appearance of definite qualities or morphological characters in the yeasts, which are transmissible and permanent These departures were so striking as to be capable of being regarded as mutational and their origin has been ascribed to the influence of the environment by experimentors of notable skill, such as Beijerinck, Winogradsky Lepeschkin Hansen and Barber It may be recalled in this connection that environic responses are generally sudden, and that the entire range of departure may be made in a single generation, at most in two or three.

Klebs who has long been concerned with the morphogenic reactions of plants, has determined a series of conditions under which the stages of mycelial development asexual zoospore and sexual or oospore formations in filamentous fungi may be inhibited or variously interchanged Much more important reactions were obtained from *Sempervivum* the live-for ever of the garden. In this plant, dense rosettes or propagative bodies are formed at the ends of some branches and inflorescences were replaced by single flowers by experimental excitation The number and arrangement of the floral organs as well as of the stamens and carpels could be altered Furthermore the deviations in question were found to be transmissible to the second or third generation in guarded seed reproductions

The results of Woltereck with *Daphnia* a small crustacean offer something by way of contrast and also serve to illustrate the necessity for continuation of parallel cultures for the purpose of comparison of divergent forms and the normal The particular group of this crustacean furnishing the experimental material is taken to be very variable and it was subjected to over feeding with the immediate result that the variability of the form of the head appeared to be widened the size of this structure being increased This disappeared when lots from the culture were restored to normal conditions in the earlier stage of the work After three or four months of over feeding the form of the head came within narrower limits and fewer *aberrants* were seen while lots returned to normal conditions showed a slower restoration of the original form of the head Two years after the cultures were begun it was found that the original head form was not displayed by young restored to normal nutrition conditions the larger helmet being persistent. It seems fairly certain that a new genotype resulted from the long-continued action of the culture medium

The fortunate experience of Zederbauer with Capsella has yielded some conclusions of exceptional importance A genotype of *Capsella Bursa-pastoris* resembling *taraxicifolium* was found on the lower plains of Asia Minor and displayed the well known characters of this form, including broad leaves, whitish flowers, and stems 30 to 40 centimeters high A highway leads from these regions to a plateau at an elevation of 2 000 to 2 400 meters. The conditions of distribution are such as to indicate that the plant has been carried up this thoroughfare by man, and in this elevated habitat it has taken on certain alpine characters including elongated roots, xerophytic leaves stems 2 to 5 centimeters high reddish flowers, with a noticeable increase of the hairiness of the entire plant. That the distributional history has been correctly apprehended seems entirely confirmed by the fact that when seeds are taken from the lowlands the alpine characters enumerated are displayed at once as a direct somatic response. When seeds are taken from plants on the elevated plateau where their ancestors may have been for many years or many centuries (perhaps as long as 2,000 years) and sowed at Vienna and in other cultures carried through four generations the leaves lose their xerophytic form and structure but the other characteristics are retained within the limits of variability The stems show an increase in average length of 1 or 2 centimeters the roots change as much, but the reproductive branches and floral organs retain their alpine

[illegible] The slight modifications undergone by [illegible] were seen to reach a maximum and to [illegible] in the latest generations cultivated. The [illegible] changes and implied functional accommodations are indubitably direct somatic responses there is no escape from the conclusion that the impress of the alpine climate on the soma has been communicated to the germ-plasm in such manner as to be transmissible and the suggestion lies near that repeated and continued excitation by climatic factors may have been the essential factor in such fixation

My own earlier work with relation to this subject consisted chiefly of ovarial treatments in which the [illegible] and accessory reproductive elements of seed [illegible] were subjected to the direct action of solutions of various kinds New combinations of characters [illegible]ting a distinct elementary species or genotype [illegible]ined in one plant and the divergent type has [illegible] to transmit its qualities in the fullest [illegible] as tested to the fifth generation Still [illegible] forms were obtained in a second genus, [illegible] progeny being lost in transference to [illegible] laboratory, while marked responses have been obtained in the extensions of these experiments upon species representing widely different morphological types in Arizona The greater majority of the tests have been made upon plants growing under natural conditions so that environmental reaction in addition to that of the specific reagents might be excluded Progenies representing many species including thousands of individuals many of which are divergent are now under observation Absolute finality of decision with respect to the standing of the new types may be reached but slowly

Gager produced chromosomic aberrations in the reducing division of *Oenothera* by irradiations and such excitation was also followed by the appearance of aberrants in the progeny the hereditary qualities of which have not been tested Using similar excitation Morgan induced the appearance of white eyes and of short wings in a pedigree culture of the fly *Drosophila ampelophila* But qualities were sex limited and mendelized when paired with the red eyes and long wings of the original type Both, however seem to be fully transmissible The first results of importance from cultures widely extended geographically have been obtained in the experiments with Leptinotarsa by Tower in which various species of these potato beetles were studied in their habitats in southern Mexico in open air and glass houses as far north as Chicago as far east as the Atlantic and as far west as the Desert Laboratory New self maintaining forms resulted from climatic excitation and the origination of species already in existence was repeated the varied effects secured being the most important contribution yet made to the subject

In addition to the conclusive observations cited there is available a great mass of information concerning experiments in which negative results were obtained the environment failing to produce any permanent effect while in other cases the living material has not been followed through a sufficient number of generations to test its heritability Thus Kammerer carried out some tests with salamanders three years ago that have the interest attached to any attempt to interpret geographic or habitat relations *Salamandra maculosa* is viviparous when it lives high in the mountains and ovo viviparous at lower levels *S atra* is an alpine form and the larvæ are large with very long gills When the latter form was kept at unusually high temperatures the larvæ produced resembled those of *S maculosa* in its lower warmer habitats. *S maculosa* kept in low temperatures and without water showed a cumulation of effects by which the characters of the young and the reproductive habits resembled those of *S atra* The conditions of these experiments are not such as to allow a definite separation of somatic and germinal effects neither was the permanency of the newly acquired habits tested to such an extent as to determine their hereditary value

In the experiments of Sumner, mice reared in a warm room were found to differ considerably from those reared in a cold room in the mean length of the tail, foot, and ear, and the differences were transmitted to the next generation The differences may be reasonably designated as being directly individual and somatic, and as having been transmitted by the germ plasm, which was not subject to the action of various temperatures in the first instance The reaction forms have an additional claim upon our attention since they are the ones which distinguish northern and southern races of many animals The crucial test of the value of the alterations induced in the mice is the one applicable to all of the experimentation on this subject a test in which two parallel series of cultures, one under the altered environment and the other under casual conditions should be kept going continuously for a long number of years lots being withdrawn from both from time to time for long continued comparative culture in normal habitat and under other conditions Effects due solely to fluctuating variability may be expected to reach a maximum and minimum within two or three years leaving the enduring effects standing alone or in such relief as to be capable of ready calibration

No little interest attaches to the evidence now accumulating to show that the hybrids between two species of plants or animals may be different in various localities or under the influence of special exciting agencies DeVries has repeatedly called attention to the fact that the composition of hybrid progenies of mutants with each other and with the parental form might be altered by nutritive conditions and the author has cited the fact that mutations were made by *Oenothera Lamarckiana* the great evening primrose in the climate of New York which had never been seen in Amsterdam Furthermore in discussing the divergent results of DeVries and myself obtained by crossing the same forms in Amsterdam and New York the suggestion was made that the manner in which the various qualities in the two parents are grouped in the progeny might be capable of a wide range of variation Many indications lead to the suggestion that the dominancy and prevalency latency and recessivity of any character may be more or less influenced by the conditions attendant upon the hybridization the operative factors might include individual qualities as well as external conditions

Tennent arranged a series of hybridizations of Echinoderms at Tortugas which yielded data of great interest in connection with the earlier conclusions of Vernon Doncaster and Herbst as to the influence of temperature and season changes upon dominance From the information derived from crosses of Hipponoë and Toxopnoustes it is clear that the dominance of the parental characters is dependent upon the alkalinity or the concentration of the OH ions The products of the trial cross fertilizations however were not reared to maturity

Much more striking evidence upon the matter has been recently obtained by Tower in intercrossing *Leptinotarsa decemlineata L multilineata L oblongata*, and other species of the potato beetles in their habitats in southern Mexico and at the desert laboratory Among other divergences one of the three first generation intermediates characteristic of these cultures was lacking from the Tucson cultures although two other such forms were included

In a comprehensive treatment of the entire subject with especial reference to modifications in dominance Tower says The experiments and observations herein given warrant the general statement that conditions external to a cross are important factors in determining the results thereof This conclusion has been worked out in both normal and hybrid crosses in crosses between races which have been created selectively, and between forms which arose as sports and the second series of experiments in synthesis is sufficient warrant for attributing to this factor a considerable importance in evolution

It is evident from the foregoing facts that the biologist is in a position to assert that external factors may affect the hereditary quality of plants and animals in a very marked manner and that agencies of various kinds may influence the results of crossing two species Furthermore the experiences at hand justify the assumption that the actual transplantation of organisms from one locality to another as a method of experimentation promises the results of highest value and widest significance especially when taken in connection with analytical laboratory cultures This method of approach is one which may yield evidence of the greatest value upon the influence of isolation and other geographical factors but is also one which allows the repetitive or mnemonic effects to be evaluated When supplemented by laboratory analyses and cultures to determine the nature of alterations induced such methods promise results of the greatest value

A series of plantations including locations from mountain tops to the seashore has been established in connection with the Desert Laboratory in accordance with this idea and in addition to the interchange of species from the various localities a number of introductions have been made from eastern America

None of the attempts hitherto made to perfect a theoretical conception which would be useful in interpreting the mechanism of environic responses have had anything more than the most limited usefulness The stimuli of climatic and many other agencies do not imply the introduction of any strange or new substances into the bodies of the organs affected These agencies might change the dissociations in such a manner as to modify the relative number of free ions and thus alter the molecular complex of the living matter in a very important manner The intricate play of enzymatic action might also be altered and any modification of the relative reaction velocities of the more important processes might result in material and permanent change especially in those cases in which external agencies interfere directly with the action of the germ plasm

The introduction of solutions into ovaries or the exposure of reproductive elements to unusual irradiation may arise from the additional liability of disturbed polarity and of modified surface tensions in the cells It is conceivable that the rearrangement or disturbance of the localizations of substances especially the mineral salts might seriously modify the capacities of the bearers of heredity These direct and material possibilities offer an adequate basis for the organization of experimental research upon the main subject as well as the means of interpretation of results without recourse to schemes of particulate inheritance or theories as to the constitution of germ plasm to which may be ascribed usefulness in the discussion of other problems in evolution

The various experimental methods used in the work on the subject and the diversity of the results obtained makes it possible to formulate some useful generalizations which may briefly be stated as follows

It is clear that some environic effects are heritable and some are not Negative or positive results of sufficient inclusiveness to permit analyses as to the nature of the exciting agency and the permanence of the response are not yet available Some of the induced characters may be retracements or regressions as the reappearance of spines in cacti or they may be awakened latencies or organizations de novo Some of the responses may result in sexual dimorphism while in others the induced characters may be sex limited The alterations induced by external agencies may be cumulative or mutative as to appearance or organization and they may be permanent upon first appearance or on the other hand may need generations of repetition before becoming fixed And lastly the changes may be orthogenetic or heterogenetic as to direction adaptive and accommodative or correlative or wholly inutile as to their functional relations

Clamp for Washing Negatives

By Z C Komorowski

The washing of paper negatives is a very delicate operation especially if one wants to do it very thoroughly without spoiling them and at the same time wash the hyphosulphite of soda entirely out We illustrate herewith a little tool which will do the work very effectively, and which commends itself on account of the cheapness and the ease of construction

Take a cork, cut it in half lengthwise, then from one of the halves cut a piece off the top as in Fig 1. Take a rubber band and fasten it tightly around the lower part of the cork to keep the two halves well together and insert a pin in the top of the uncut half, Fig. 2 The cork cut in this way will act as a clamp and the two halves can be opened more or less as desired

To use this clamp open it by pressing lightly the top insert the paper in the lower opening and then release Put the whole in the wash basin The cork

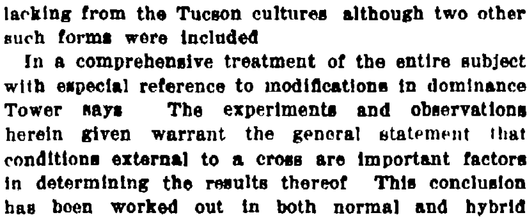

Fig. 1 Fig 2 Fig. 3

Clamp Made of Cork for Use in Washing Negatives

will float on the surface and the hyposulphite will dissolve and sink to the bottom After you are sure that the washing has been properly done, pick up the cork and the negative and hang them by the pin to drip on a wire or cord stretched between two supports (Fig 3)

From the time the negative is inserted in the clamp until it is taken out dry one need not touch them with the hands thus avoiding the danger of a scratch or a blotch

Inspection of nursery stock imported into the United States from foreign countries has been an important item in the year's work Much of this stock destined to many of the States and the District of Columbia when inspected was found to be seriously infested with brown tail moths or other injurious insects and nearly 300 such shipments have been destroyed Through the efforts of the Agricultural Department some of the offending countries have adopted inspection methods and their shipments are likely to be less dangerous in the future

Making Money Out of Bees—II*

Keeping Bees for Pleasure and Profit

By E F Phillips, Ph D, in charge of Bee Culture, Bureau of Entomology

Concluded from Supplement No 1833, page 110

DIRECTIONS FOR GENERAL MANIPULATIONS

Bees should be handled so that they will be little disturbed in their work As much as possible stings should be avoided during manipulation This is true not so much because they are painful to the operator but because the odor of poison which gets into the air irritates the other bees and makes them more difficult to manage For this reason it is most advisable to wear a black veil (Fig 4) over a wide brimmed hat and to have a good smoker (Fig 1) Experienced bee keepers often dispense with these but the beginner should not Gloves however are usually more an inconvenience than otherwise Gauntlets or rubber bands around the cuffs keep the bees from crawling up the sleeve It is best to avoid black clothing since that color seems to excite bees a black felt hat is especially to be avoided

The bee keeper should manipulate without exhibiting fear This is not because the bees recognize the fact that the operator is afraid of them as some claim but because superfluous quick movements tend to irritate the bees The hive should not be jarred or disturbed any more than necessary Rapid movements are objectionable because with their peculiar eye structure bees probably perceive motion more readily than they do objects Persons not accustomed to bees on approaching a hive often strike at bees which fly toward them or make some quick movement of the head or hand to avoid the sting which they fear is to follow This is just what should not be done for the rapid movement even if not toward the bee is far more likely to be followed by a sting than in remaining quiet.

The best time to handle bees is during the middle of warm days particularly during a honey flow Never handle bees at night or on cold wet days unless absolutely necessary The work of a beginner may be made much easier and more pleasant by keeping gentle bees Caucasians Carniolans Banats and

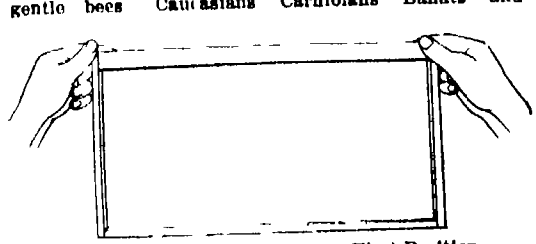

Fig 11—Handling the Frame First Position

strains of Italians ordinarily do not sting much unless unusually provoked or except in bad weather Common black bees or crosses of blacks with other races are more irritable It may be well worth while for the beginner to procure gentle bees while gaining experience in manipulation Later on this is less important for the bee keeper learns to handle bees with the least inconvenience to himself or to them

Before opening a hive the smoker should be lighted and the veil put on A few puffs of smoke directed into the entrance will cause the bees to fill themselves with honey and will drive back the guards The hive cover should be raised gently if necessary being pried loose with a screw-driver or special hive tool As soon as a small opening is made more smoke should be blown in on the tops of the frames or if a mat covering for the frames is used the cover should be entirely removed and one corner of the mat lifted to admit smoke It is not desirable to use any more smoke than just enough to subdue the bees and keep them down on the frames At any time during manipulation if they become excited more smoke may be used Do not stand in front of the entrance but at one side or the back

After the frames are exposed they may be loosened by prying with the hive tool and crowded together a little so as to give room for the removal of one frame In cool weather the propolis (bee glue) may be brittle. Care should be exercised not to loosen this with a jar The first frame removed can be leaned against the hive so that inside there will be more room for handling the others During all manipulations bees must not be mashed or crowded for that irritates the colony greatly and may make it necessary to discontinue operations Undue crowding may also mash the queen If bees crawl on the hands they may be gently brushed off or thrown off

In examining a frame always hold it over the hive, so that any bees or queen which fall may drop into it. Freshly gathered honey also often drops from the frame and if it falls in the hive the bees can quickly clean it up whereas if it drops outside it is untidy and may cause robbing If a frame is temporarily leaned against the hive it should be placed in a nearly upright position to prevent breakage and leakage of

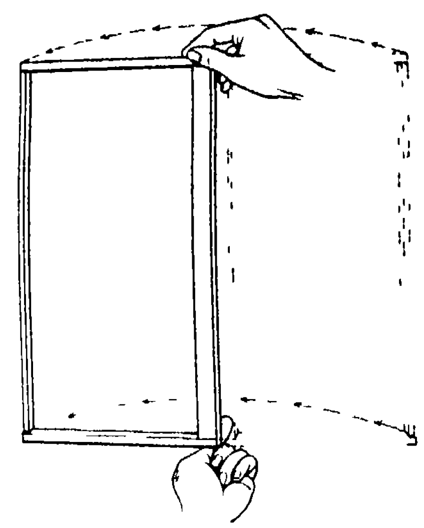

Fig 12—Handling the Frame Second Position

honey The frame on which the queen is located should not be placed on the ground for fear she may crawl away and be lost It is best to lean the frame on the side of the hive away from the operator so that bees will not crawl up the legs

In handling frames the comb should always be held in a vertical position especially if it contains much honey When a frame is lifted from the hive by the top bar one side is exposed to the operator with the comb placed vertically (Fig 11) To examine the reverse side raise one end of the top bar until it is perpendicular (Fig 12) turn the frame on the top bar as an axis until the reverse side is in view and then lower to a horizontal position with the top bar below (Fig 13) In this way there is no extra strain on the comb and the bees are not irritated This care is not so necessary with wired combs, but it is a good habit to form in handling frames

It is desirable to have combs all of worker cells to reduce the amount of drone brood The use of full sheets of foundation will bring this about and is also of value in making the combs straight, so that bees are not mashed in removing the frame It is extremely difficult to remove combs built crosswise in the hive and this should never be allowed to occur Such a hive is even worse than a plain box hive Extra inside fixtures should be avoided as they tend only to impede manipulation The hive should also be placed so that the entrance is perfectly horizontal and a little lower than the back of the hive The frames will then hang in a vertical position and the outer ones

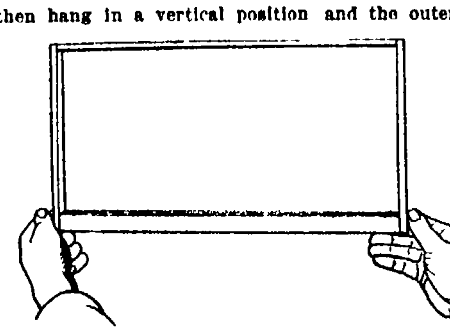

Fig 13—Handling the Frame Third Position

will not be fastened to the hive body if properly spaced at the top

Various remedies for bee stings have been advocated but they are all useless The puncture made by the sting is so small that it closes when the sting is removed and liquids cannot be expected to enter The best thing to do when stung is to remove the sting as soon as possible without squeezing the poison sac, which is usually attached This can be done by scraping it out with a knife or finger nail. After this is done the injured spot should be let alone and not rubbed with any liniment. The intense itching will soon disappear any irritation only serves to increase the after swelling

In placing frames in the hive great care should be exercised that they are properly spaced. Some frames are self spacing having projections on the side, so that when placed as close as possible they are the correct distance apart. These are good for beginners or persons who do not judge distances well and are preferred by many professional bee keepers. If the spaced frames are used they should be 1⅜ inches from center to center A little practice will usually enable anyone to space quickly and accurately. Careful spacing is necessary to prevent the building of combs of irregular thickness and to retard the building of pieces of comb from one frame to another

A beginner in bee keeping should by all means, if possible visit some experienced bee keeper to get suggestions in handling bees. More can be learned in a short visit than in a considerably longer time in reading directions and numerous short cuts which are acquired by experience will well repay the trouble or expense of such a visit. Not all professional bee keepers manipulate in the very best way but later personal experience will correct any erroneous information Above all personal experimenting and a study of bee activity are absolute necessities in the practical handling of bees

TRANSFERRING

In increasing the apiary it is sometimes best to buy colonies in box hives on account of their smaller cost and to transfer them to hives with movable frames This should be done as soon as possible, for box hive colonies are of small value as producers. The best time to transfer is in the spring (during fruit bloom in the North) when the amount of honey and the population of the colony are at a minimum.

Transferring should not be delayed until spring merely because that season is best for the work It may be done at any time during the active season but,

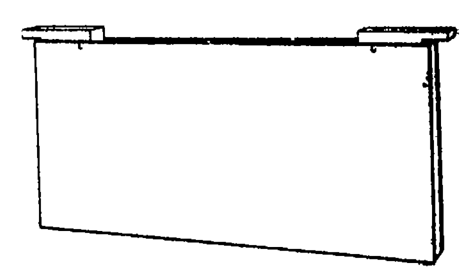

Fig 14—Division board Feeder to be Hung in Hive in Place of Frame

whenever possible during a honey flow to prevent robbing If necessary it may be done in a tent such as is often used in manipulating colonies By choosing a time of day when the largest number of bees are in the field the work will be lessened

The box hive should be moved a few feet from its stand and in its place should be put a hive containing either full sheets of foundation or empty combs The box hive should be turned upside down and a small empty box fitted on it. By drumming continuously on the box hive for a considerable time the bees will be made to desert their combs and go to the upper box and when most of them are clustered above the box may be carried to the new hive and the bees dumped in front of the entrance The queen will usually be seen as the bees enter the hive, but, in case she has not left the old combs more drumming will induce her to leave It is necessary that the queen be in the hive before this manipulation is finished The old box hive containing brood may now be placed right side up in a new location and in twenty-one days all of the worker brood will have emerged and probably some new queens will have been reared These bees may then be drummed out and united with their former hive mates by smoking the colony and the drummed bees vigorously and allowing the latter to enter the hive through a perforated zinc to keep out the young queens The wax in the box hive may then be melted up and any honey which it may contain used as the bee keeper sees fit. By this method good straight combs are obtained If little honey is being gathered, the colony in the hive must be provided with food

If, on the other hand the operator desires to save the combs of the box hive, the bees may be drummed into a box and the brood combs and other fairly good combs cut to fit frames and tied in place or held with rubber bands, strings, or strips of wood until the bees can repair the damage and fill up the breaks,

* Farmers Bulletin No 397 United States Department of Agriculture

[illegible] then be hung in a hive on the old [illegible] allowed to go in. The cutting of [illegible] brood with more or less bees on [illegible] job, and since the combs so ob[illegible] of little value in an apiary the [illegible] recommended

[illegible] take up their abode in walls of [illegible] necessary to remove them to [illegible] melting combs If the cavity in [illegible] built can be reached the method [illegible] that of transferring, except that [illegible] practical and the bees must simply [illegible] smoke and the combs cut out with [illegible]

[illegible] which is often better is to place a [illegible] the entrance to the cavity, so that [illegible] out, but cannot return A cone of [illegible] inches high with a hole at the [illegible] enough for one bee to pass will serve [illegible] or a regular bee escape such as are [illegible] may be used A hive which they can [illegible] placed beside the entrance The queen is [illegible] this way and, of course, goes right [illegible] but as the colony is rapidly reduced in [illegible] brood decreases As brood emerges the younger bees leave the cavity and join the bees in the hive, until finally the queen is left practically alone. A new queen should be given to the bees in the hive as soon as possible and in a short time they are fully established in their new quarters After about four weeks, when all or nearly all of the brood in the cavity has emerged the bee escape should be removed and as large a hole made at the entrance of the cavity as possible The bees will then go in and rob out the honey and carry it to the hive leaving only empty combs. The empty combs will probably do no damage, as moths usually soon destroy them and they may be left in the cavity and the old entrance care fully closed to prevent another swarm from taking up quarters there.

In transferring bees from a hollow tree the method will depend on the accessibility of the cavity Usually it is difficult to drum out the bees and the combs can be cut out after subduing the colony with smoke

UNITING

Frequently colonies become queenless when it is not practicable to give them a new queen and the best practice under such conditions is to unite the queenless bees to a normal colony If any colonies are weak in the fall even if they have a queen safe wintering is better insured if two or more weak colonies are united, keeping the best queen Under various other conditions which may arise the bee keeper may find it desirable to unite bees from different colonies Some fundamental facts in bee behavior must be thoroughly understood to make this a success

Every colony of bees has a distinctive colony odor and by this means bees recognize the entering of their hive by bees from other colonies and usually resent it If, however a bee comes heavily laden from the field and flies directly into the wrong hive without hesitation it is rarely molested In uniting colonies the separate colony odors must be hidden and this is done by smoking each colony vigorously It may at

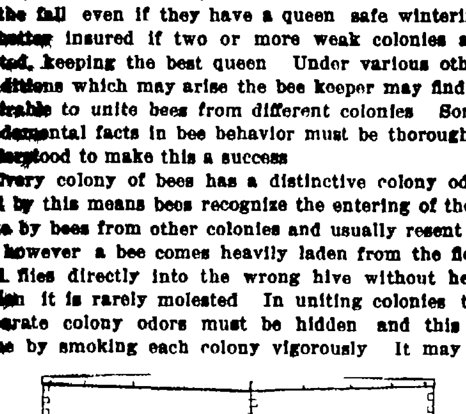

Fig. 15—Feeder Set in Collar under Hive Body

times be desirable to use tobacco smoke which not only covers the colony odor but stupefies the bees somewhat. Care should be taken not to use too much tobacco, as it will completely overcome the bees The queen to be saved should be caged for a day or two to prevent the strange bees from killing her in the first excitement.

Another fact which must be considered is that the bees of a colony carefully mark the location of their own hive and remember that location for some time after they are removed If, therefore two colonies in the apiary which are not close together are to be united, they should be moved gradually nearer, not more than a foot at a time, until they are side by side so that the bees will not return to their original locations and be lost. As the hives are moved gradually the [illegible] are noted and no such loss occurs. As a [illegible] a board should be placed in front of the entrance [illegible] position, or brush and weeds may be thrown down so that when the bees fly out they recognize the fact that there has been a change and accustom themselves to the new place If uniting can be done during a honey flow there is less danger of loss by bees fighting or if done in cool weather when the bees are not actively rearing brood, the colony odors are diminished and the danger is reduced

It is an easy matter to unite two or more weak swarms to make one strong one for during swarming the bees have lost their memory of the old location are full of honey and are easily placed wherever the bee keeper wishes. They may simply be thrown together in front of a hive Swarms may also be given to a newly established colony with little difficulty

PREVENTING ROBBING IN THE APIARY

When there is no honey flow bees are inclined to rob other colonies and every precaution must be taken to

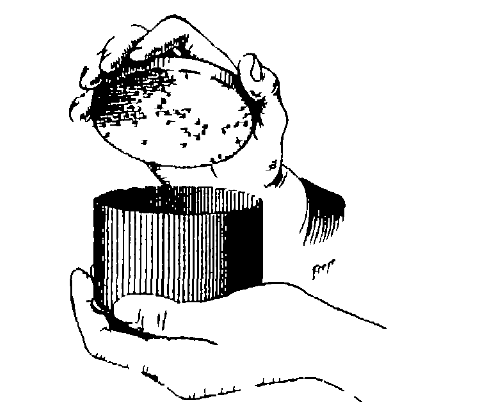

Fig 16—Pepper box Feeder for Use on Top of Frames

prevent this Feeding often attracts other bees and if there are indications of robbing the sirup or honey should be given late in the day As soon as robbing begins manipulation of colonies should be discontinued the hives closed and if necessary the entrances contracted as far as the weather will permit If brush is thrown in front of the entrance robbers are less likely to attempt entering At all times honey which has been removed from the hives should be kept where no bees can get at it so as not to incite robbing

FEEDING

During the spring manipulations in preparing bees for winter and at other times it may be necessary to feed bees for stimulation or to provide stores *Honey from an unknown source should never be used* for fear of introducing disease and sirup made of granulated sugar is cheapest and best for this purpose The cheaper grades of sugar or molasses should never be used for winter stores The proportion of sugar to water depends on the season and the purpose of the feeding For stimulation a proportion of one fourth to one-third sugar by volume is enough and for fall feeding especially if rather late a solution containing as much sugar as it will hold when cold is best There seems to be little advantage in boiling the sirup Tartaric acid in small quantity may be added for the purpose of changing part of the cane sugar to invert sugar thus retarding granulation The medication of sirup as a preventive or cure of brood disease is often practiced but it has not been shown that such a procedure is of any value If honey is fed it should be diluted somewhat the amount of dilution depending on the season If robbing is likely to occur feeding should be done in the evening

Numerous feeders are on the market, adapted for different purposes and methods of manipulation (Figs 14 15 16) A simple feeder can be made of a tin pan filled with excelsior or shavings (Fig 17) This is filled with sirup and placed on top of the frames in a super or hive body It is advisable to lean pieces of wood on the pan as runways for the bees and to attract them first to the sirup either by mixing in a little honey or by spilling a little sirup over the frames and sticks It may be stated positively that it does not pay financially or in any other way to feed sugar sirup to be stored in sections and sold as comb honey Of course such things have been tried but the consumption of sugar during the storing makes the cost greater than the value of pure floral honey

SPRING MANAGEMENT

The condition of a colony of bees in the early spring depends largely on care in the preceding autumn and in the method of wintering If the colony has wintered well and has a good prolific queen preferably young the chances are that it will become strong in time to store a good surplus when the honey flow comes

The bees which come through the winter reared the previous autumn are old and incapable of much work As the season opens they go out to collect the early nectar and pollen, and also care for the brood which hatches from the eggs laid by the queen The amount of brood is at first small and as the new workers emerge they assist in the brood rearing so that the extent of the brood can be gradually increased until it reaches the maximum at the beginning of the summer The old bees die off rapidly

If brood rearing does not continue late in the fall so that the colony goes into winter with a large percentage of young bees the old bees may die off in the spring faster than they are replaced by the emerging brood This is known as spring dwindling A remedy for this may be applied by feeding if necessary the autumn before or keeping up brood rearing by some other means as late as possible

If spring dwindling begins however it can be diminished somewhat by keeping the colony warm and by stimulative feeding so that all the energy of the old bees may be put to the best advantage in rearing brood to replace those dying off The size of the brood chamber can also be reduced to conserve heat

It sometimes happens that when a hive is examined in the spring the hive body and combs are spotted with brownish yellow excrement This is an evidence of what is commonly called dysentery The cause of this trouble is long-continued confinement with a poor quality of honey for food Honey dew honey and some of the inferior floral honeys contain a relatively large percentage of material which bees cannot digest and if they are not able to fly for some time the intestines become clogged with fæcal matter and a diseased condition results Bees never normally deposit their fæces in the hive The obvious preventive for this is to provide the colony with good honey or sugar sirup the previous fall Dysentery frequently entirely destroys colonies but if the bees can pull through until warm days permit a cleansing flight they recover promptly

Bees should not be handled in the early spring any more than necessary for to open a hive in cool weather wastes heat and may even kill the brood by chilling The hive should be kept as warm as possible in early spring as an aid to brood rearing It is a good practice to wrap hives in black tar paper in the spring not only that it may aid in conserving the heat of the colony but in holding the sun s heat rays as a help to the warmth of the hive This wrapping should be put on as soon as an early examination has shown the colony to be in good condition and there need be no hurry in taking it off A black wrapping during the winter is not desirable as it might induce brood rearing too early and waste the strength of the bees

As a further stimulus to brood rearing many bee keepers practice stimulative feeding of sugar sirup in early spring This produces the same effect as a light honey flow does and the results are good Others prefer to give the bees such a large supply of stores in the fall that when spring comes they will have an abundance for brood rearing and it will not be necessary to disturb them in cool weather Both ideas are good but judicious stimulative feeding usually more than pays for the labor Colonies should be fed late in the day so that the bees will not fly as a result of

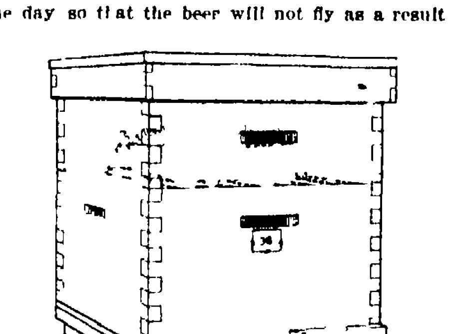

Fig 17—Pan in Super Arranged for Feeding

this and so that robbing will not be started When the weather is warmer and more settled the brood cluster may be artificially enlarged by spreading the frames so as to insert an empty comb in the middle The bees will attempt to cover all the brood that they already had and the queen will at once begin laying in the newly inserted comb thus making a great increase in the brood This practice is desirable when carefully done but may lead to serious results if too much new brood is produced A beginner had better leave the quantity of brood to the bees

It is desirable early in the season before any preparations are made for swarming to go through the apiary and clip one wing of each queen so that if a swarm issues the queen cannot fly and the bees can be easily returned to the old stand This should be done before the hive becomes too populous It is perhaps best to clip queens as they are introduced but some colonies may rear new ones without the knowledge of

the owner and a spring examination will insure no escaping swarms.

Queens sometimes die during the winter and early spring and since there is no brood from which the bees can replace them, the queenless colonies are hopelessly queenless Such colonies are usually restless and are not active in pollen gathering If on opening a colony it is found to be without a queen and reduced in numbers it should be united with another colony by smoking both vigorously and caging the queen in the queen right colony for a day or two to prevent her being killed A frame or two of brood may be added to a queenless colony not only to increase its strength but to provide young brood from which they can rear a queen Bee keepers in the North can frequently buy queens from southern breeders early in the spring and naturally this is better than leaving the colony without a queen until the bees can rear one as it is important that there be no stoppage in brood rearing at this season

SWARM MANAGEMENT AND INCREASE

The excessive rearing of brood at the wrong season or increase in the number of colonies greatly reduces the surplus honey crop by consumption The ideal to which all progressive bee keepers work when operating simply for honey is to stimulate brood rearing to prepare bees for gathering to retard breeding when it is less desirable and to prevent swarming Formerly the measure of success in bee keeping was the amount of increase by swarming but this is now recognized as being quite the contrary of success

The stimulation of brood rearing in the spring however makes it more likely that swarming will occur so that the operator must counteract that tendency This is especially true in comb-honey production Very few succeed in entirely preventing swarming but by various methods the situation can be largely controlled

When a swarm issues it usually first settles on a limb of a tree or bush near the apiary It was formerly common to make a noise by beating pans or ringing bells in the belief that this causes the swarm to settle There is no foundation for such action on the part of the bee keeper If the bees light on a small limb that can be spared it may simply be sawed off and the bees carried to the hive and thrown on a sheet or hive cover in front of the entrance If the limb cannot be cut, the swarm can be shaken off into a box or basket on a pole and hived If the bees light on the trunk of a tree or in some inaccessible place they can first be attracted away by a comb preferably containing unsealed brood In these manipulations it is not necessary to get all the bees but if the queen is not with those which are put in the hive the bees will go into the air again and join the cluster

If a queen is clipped as recommended under Spring management the swarm will issue just the same but the queen not being able to fly will simply wander about on the ground in front of the hive where she can be caught and caged The parent colony can then be removed to a new stand and a new hive put in its place The bees will soon return and the queen can be freed among them as they enter The field bees on returning will enter the new hive with the swarm thus decreasing still more the parent colony and making a second swarm less probable. To make sure of this however all queen cells except one good one can be removed soon after the swarm issues. To hold a swarm it is desirable to put one frame containing unsealed brood in the new hive The other frames may contain full sheets or starters of foundation or drawn combs Usually comb-honey supers or surplus bodies for extracting frames will have been put on before swarming occurs These are given to the swarm on the old stand and separated from the brood chamber by queen-excluding perforated zinc

When clipping the queen's wing is not practised swarms may be prevented from leaving by the use of queen traps of perforated zinc (Fig 6) These allow the workers to pass out, but not drones or queens which on leaving the entrance, pass up to an upper compartment from which they cannot return These are also used for keeping undesirable drones from escaping and the drones die of starvation When a swarm issues from a hive provided with a queen trap the queen goes to the upper compartment and remains there until released by the bee keeper The workers soon return to the hive When the operator discovers the queen outside the colony may be artificially swarmed to prevent another attempt at natural swarming A queen trap should not be kept on the hive all the time for fear the old queen may be superseded and the young queen prevented from flying out to mate

ARTIFICIAL SWARMING

If increase is desired it is better to practice some method of artificial swarming and to forestall natural swarming rather than be compelled to await the whims of the colonies The situation should be under the control of the bee keeper as much as possible The bees combs and brood may be divided into two nearly equal parts and a queen provided for the queenless portion or small colonies called nuclei may be made from the parent colony so reducing its strength that swarming is not attempted These plans are not as satisfactory as shaken swarms since divided colonies lack the vigor of swarms

A good method of artificially swarming a colony is to shake most of the bees from the combs into a new hive on the old stand with starters (narrow strips) of foundation The hive containing the brood with some bees still adhering is then moved to a new location If receptacles for surplus honey have been put on previously as they generally should be they should now be put over the artificial swarm separated from the brood compartment by perforated zinc

This method of artificially swarming (usually called by bee keepers shook swarming) should not be practiced too early since natural swarming may take place later The colony should first have begun its preparations for swarming The method is particularly useful in comb-honey production The bees may be prevented from leaving the hive by the use of a drone trap (Fig 6) or by putting in one frame containing unsealed brood Some bee keepers prefer using full sheets of foundation or even drawn combs for the artificial swarm but narrow strips of foundation have some advantages By using narrow strips the queen has no cells in which to lay eggs for a time, thus reducing brood rearing but since by the time artificial swarming is practised the profitable brood rearing is over, this is no loss but rather [illegible] also in the brood compartment so [illegible] gathering workers can deposit fr[illegible] consequently put it above in the [illegible] the combs below are built out and [illegible] creased. Late the colony is allowed to put honey in the brood combs for its winter supply. If no increase is desired, the bees which emerge from the removed brood combs may later be united with the original swarm and by that time there will usually be little danger of natural swarming

PREVENTION OF SWARMING.

Unless increase is particularly desired, both natural and artificial swarming should be [illegible] as far as possible so that the energy of the bees will go into the gathering of honey [illegible] overheated hives are particularly [illegible] ing this tendency may be largely [illegible] by giving plenty of ventilation and additional room in the hive. Shade is also a good preventive of swarming. [illegible] space in the hive may be furnished by adding more hive bodies and frames or by frequent extracting so that there may be plenty of room for brood rearing and storage at all times. These [illegible] are, of course particularly applicable to extracted-honey production

To curb the swarming impulse frequent examinations of the colonies (about every week or ten days during the swarming season) for the purpose of cutting out queen cells is a help, but this requires considerable work and since some cells may be overlooked and particularly since it frequently fails in spite of the greatest care, it is not usually practised Requeening with young queens early in the season when possible generally prevents swarming.

Swarming is largely due to crowded brood chambers, and since eggs laid immediately before and during the honey flow do not produce gatherers, several methods have been tried of reducing the brood. The queen may either be entirely removed or be caged in the hive to prevent her from laying. In either event the bees will usually build queen cells to replace her, and these must be kept cut out These plans would answer the purpose very well were it not for the fact that queenless colonies often do not work vigorously Under most circumstances these methods cannot be recommended A better method is to remove brood about swarming time and thus reduce the amount. There are generally colonies in the apiary to which frames of brood can be given to advantage.

In addition to these methods various non-swarming devices have been invented and later a non-swarming hive so constructed that there is no opportunity for bees to form a dense cluster The breeding of bees by selecting colonies with less tendency to swarm has been suggested but nothing has been accomplished along that line

On the whole the best methods are the giving of plenty of room shade ventilation to colonies run for extracted honey and ventilation shade and artificial swarming of colonies run for comb honey Frequent requeening (about once in two years) is desirable for other reasons and requeening before swarming time helps in the solution of that difficulty

(To be continued)

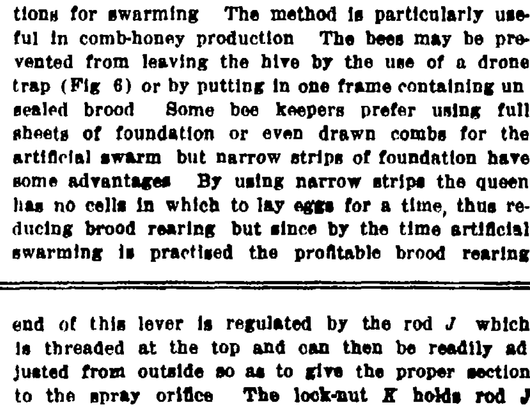
A Variable-Speed Carbureter

By the Paris Correspondent of the SCIENTIFIC AMERICAN

The extent to which the automobile has come into use for cab service in large cities has given rise to a somewhat difficult problem in carbureter design Vehicles of this kind are necessarily driven at low speed over a considerable portion of their travel owing to the congestion of city traffic Now, ordinarily a carburetor designed for normal speeds will not function satisfactorily and economically at low speeds

One solution of the problem is to provide a double carbureter which in one setting is adapted for high speed work and in another setting gives good economy at low speed Such is the new Longuemare carbureter recently tested in the laboratories of the Paris Automobile Club and described by M G Lumet chief engineer of that laboratory

The device is shown in section in our illustration It consists of the usual float-feed chamber attached to the carbureter proper From the feed chamber the gasoline passes into a cylindrical tube B through a series of holes in a stopper L fitted into the lower end of the tube Fixed on the stopper is a rod G terminating above in a point At the upper part of the tube there is a second set of holes M by which the gasoline reaches the spray nozzle F This latter is a small piece screwed on to its seat and receives the pointed end of the rod forming a needle valve controlling the spray orifice The stopper L has a sliding fit in the tube and is normally pushed down by the spring H against the action of the horizontal lever, engaging the lower extremity of L. The other end of this lever is regulated by the rod J which is threaded at the top and can then be readily adjusted from outside so as to give the proper section to the spray orifice The lock-nut K holds rod J in position If desired the nut can have ratchet



Section Through Two-speed Carbureter

teeth cut in it, so as to fix the screw in a certain number of definite positions, and this will give corresponding standard sections for the spray

The air enters at the base of the carbureter through openings N, arranged around the cylinder From the lower part it mounts through the narrowed portion P so that it passes by the spray orifice at the maximum speed. The usual carbureting action takes place and the air and gas mixture passes by D to the motor The portion D acts as valve, and can be turned by an outside handle in the manner of a gas cock, when it is desired to set the carbureter for low speed As above described, the carbureter is designed to work under normal conditions of speed The second part of the carbureter comes into use for the slow motor speed as well as for starting the automobile By turning the key D from right to left the orifice is gradually cut down and finally reduced to zero and the gas is now cut off from the motor. But at this moment a notch Q, in the key comes to the bottom and uncovers another passage leading from the carbureter to the motor, as will be seen on the left of the drawing The sections for the screw passage are calculated to suit the conditions of slow motor speed A nozzle O lies just opposite the spray orifice its distance from the spray being controlled by a screw adjustment and arranged to suit the conditions of slow running as nearly as possible This adjustment means is further supplemented by working the joint valve P so as to cut off the gas inlet more or less. The carbureter is heated by hot water jacket R fed from the pipe S

The carbureter here described is built for two settings. Evidently the same general principle could be applied to design an apparatus giving a greater number of graded settings

Preservation of Drawings (in pencil and India ink).—They should be coated with collodion (photographic), after 2 per cent of stearine has been added to it. The drawing is laid on a sheet of glass or a board, and the collodion poured over it. After 10 to 20 minutes, the drawing is dry and perfectly white.

The Relation of Light to the Production of Sugar in Beets

There has been found a great deal of variation in the sugar yield of certain high grade strains of sugar beets when grown in different localities The variations were such as could not be accounted for by the differences in the soil in methods of cultivation or in fertilizers During the past two seasons (1909 1910) experiments were conducted in Utah to determine to what extent the differences in the amount of light were responsible for the differences in the amount of sugar

A long row of beets planted under the usual field conditions was selected A portion of this row was shaded with white bunting another portion with two thicknesses of bunting a third with three thicknesses and the remainder of the row left open to the full light Of course the shading resulted also in a cutting off of the heat rays from the sun so that it is impossible to attribute all of the differences found to a reduction in the light but the temperature differences were very slight compared to the light differences

The relative light intensities based on the actual duration of bright sunshine and diffused daylight throughout the entire season ranged from 100 for the open portion of the row to about 10 for the part most shaded the temperature range was from 112 deg F in the open row in full sunshine to 94 deg F in the most shaded part The beets ranged in weight from an average of 27¾ oz to 1¾ oz and the sugar content varied from 18 oz to 0 1 oz—that is in the full light there was produced more than twenty five times as much sugar as in the most shaded region

It appears also that not only is the actual amount of sugar affected by the amount of light, but even the purity of the juice this ranged from 76 7 per cent at one end to 61 per cent in the most shaded portion Not only then would the farmer get a better yield from growing the beets in fields or localities with a maximum of light exposure but the beets raised under such conditions could be more economically utilized at the sugar mill

Moire Decoration on Sheet Tin.—a Carefully warm evenly tinned sheet iron (sheet tin) until the tin coating is just melting (to about 536 deg) and quickly throw it into the following mixture 2 parts chloride of tin in 4 parts water 1 part commercial nitric acid and 2 parts hydrochloric acid After drying coat, if desired with shellac solution tinted with aniline color b If a piece of tin be heated in one place by contact with a hot soldering iron as over the flame of a light, the tinning within a circular space will be melted and after cooling and etching with hydrochloric acid will display a fairly regular radial star shaped figure If we pass over the sheet tin with the soldering iron or the flame in a line grain-ear shaped strips will result and by this means garlands names and ornaments can be produced on the tin If it is desired to cover a sheet uniformly with crystals it should be evenly heated over a coal fire until the tin begins to melt If water is then thrown on it, in a fine spray each drop of water falling on it will form a center of crystallization If the water is caused to flow by inclining the plate a striped or veined pattern will result If the heated plate is immersed in an inclined direction in cold water a fine moiré of granite-like design will be produced. After [illegible] it [illegible] be etched by waxing in dilute hydroch[illegible] to [illegible] some nitric acid has been added [illegible] then to be washed with clean water [illegible] some caustic potash, to remove an[illegible] that may have formed and finally agai[illegible] with clean water Finally the moiré is co[illegible] with a transparent varnish

Considerable interest in being [illegible] in Norway and Sweden as regards the m[illegible] of steel by the electric furnace process. T[illegible] daily papers state that one of the lea[illegible] of the Great Swedish Copper Company [illegible] has been engaged in the construction [illegible] electric steel furnace on the Grönwall type wh[illegible] designed for 4 000 horse-power and he expects [illegible] operating it in the near future Owing to the [illegible] position which he occupies among iron m[illegible] the announcement caused somewhat of a stir However, other steel furnaces are erecting in the Sc[illegible] region. The Swedish syndicate of iron man[illegible] known as Elsenkontor is building a 2 500 horse-power electric steel furnace of the same type It is located at the Trolhattan fall near the great hy[illegible] plant The sum of 250 000 crowns has been [illegible] for testing the adaptability of various kinds of [illegible] ores for the process. Matters are also active in Norway and by next spring it is expected to have the electric iron and steel plant in operation on the Hardangar [illegible] has an output of about 4 000 horse-power Two of the leading Russian iron works are taking up the question of electric steel manufacture and they have purchased the rights for the Heroult [illegible] pro-cess One of these firms is the Sormovo Iron Works and the other the Makievka Blast Furnaces and Steel Works in the Donetz basin

THE SCIENTIFIC AMERICAN CYCLOPEDIA OF FORMULAS

The Most Complete and Authoritative Book of Receipts Published

Partly Based on the Twenty Eighth Edition of The Scientific American Cyclopedia of Receipts, Notes and Queries

Edited by **ALBERT A. HOPKINS**

Query Editor of the Scientific American

THIS is practically a ***new book*** and has called for the work of a corps of specialists for more than two years Over 15 000 of the most useful formulas and processes, carefully selected from a collection of nearly 150 000 are contained in this most valuable volume nearly every branch of the useful arts being represented Never before has such a large collection of really valuable formulas, useful to everyone been offered to the public The formulas are classified and arranged into chapters containing related subjects, while a complete index, made by professional librarians, renders it easy to find any formula desired

"As Indispensable as a Dictionary and More Useful"

FOLLOWING IS A LIST OF THE CHAPTERS:

I Accidents and Emergencies.
II Agriculture
III Alloys and Amalgams
IV Art and Artists Material
V Beverages, Non Alcoholic and Alcoholic
VI Cleansing, Bleaching, Renovating and Protecting
VII Cements, Glues, Pastes and Mucilages
VIII Coloring of Metals, Bronzing, etc
IX Dyeing.
X Electrometallurgy and Coating of Metals.
XI Glass
XII Heat Treatment of Metals.
XIII Household Formulas
XIV Ice Cream and Confectionery
XV Insecticides, Extermination of Vermin
XVI Lapidary Art, Bone, Ivory etc.
XVII Leather
XVIII Lubricants.
XIX. Paints, Varnishes, etc.
XX Photography
XXI Preserving, Canning, Pickling, etc.
XXII Rubber Gutta-Percha and Celluloid
XXIII Soaps and Candles.
XXIV Soldering.
XXV Toilet Preparations, including Perfumery
XXVI Waterproofing and Fireproofing
XXVII Writing Materials.

Appendix: Miscellaneous Formulas; Chemical Manipulation; [illegible] Weights and Measures, Index

Selection and Treatment of Alloy Steels for Automobiles

Why You Can Buy a Good Car for Little Money

By Henry Souther

A PECULIAR remark during the last few years has been to the effect that the steel business has advanced and changed rapidly and that the incentive is found in the manufacture of automobiles This condition still continues and the evolution within the construction of the car itself is no less rapid Design materials style and selling methods are all involved

Curiously enough it would seem at first glance that the choice of materials is involved in all of these four branches of the industry and not in the one or two as would seem natural

The reasonable use of materials is to be the theme of this paper Many considerations are involved in looking back to the beginning of the automobile industry and it seems necessary to do this in order that the evolution may be followed as far as materials are concerned

At the beginning every faculty of designer and builder was focused on the production of an operative machine Materials were disregarded so long as they would help build the vehicle and were obviously steel brass aluminum or wood All were too busy to regard the quality Generally speaking there were available from the stand point of the automobile builder Bessemer steel, open hearth steel and cast or crucible steel Variations within these classes were regarded as unimportant and heat treatment was an unknown term Certainly only theoretical at the best and therefore useless to a practical man

Now these same men have among them those who state that the heat treating department of the works is the most important of all This is not so with all yet; there are some who still balk at talk of critical points, recalescence pyrometers and the like The evolution is rapid however and this class will soon disappear

After a year or two the cars operated very well; at least well enough to run long enough to break parts crank shafts axles and steering parts Then a little attention was directed toward steel There seemed to be no clear idea of a cure If a steel part broke with an appearance of brittleness good old wrought iron was tried as a sure cure If bending occurred tool steel was tried in some cases and medium carbons (0 50 per cent) in others it being understood that high carbons were stronger but brittle The natural or annealed state was the only one known to the automobile industry at this time

At about this time nickel steel was mentioned as a possibility It had been used or as some said advertised as used for bicycle construction But generally it was regarded as something fancy and not worthy of the consideration of hard headed men It was expensive hard to work and no good anyway in the opinion of many

So when alloys came along in earnest and were offered systematically by steel agents they had a hard time making any progress The high prices quoted were laughed at There seemed to be no chance that alloys would ever be given a fair trial After some little time and persistence by the steel agent alloy steels were tried and proven good even at 15 cents per pound Some designs required alloy steels to stop breakage the result of small dimensions sharp corners where fillets should be and similar mistakes In this way the alloy or perhaps the high quality carbon steel had a chance to make good in a spectacular way These instances helped the spread of high grade steels until now the pendulum has swung too far and alloys are used where they need not be and money is thereby wasted There is indication of a notion that an alloy steel is a cure all and that if needed in one part that it must be a fine thing in all parts

Unfortunately the art of heat treatment has not spread as fast as alloy steels have and many cases exist where very expensive steels have been put into cars in an annealed or forged condition; which is absolutely unreasonable The alloy steel is no cure all and must be used intelligently if any compensation for increased cost is to be realized

A case in point is found in an engine crank shaft It is large for the duty If it is made of an alloy treated up to 100 000 lbs per sq inch or more when 60 000 lbs. would suffice there has been no gain to the automobile and there has been a money waste It is not generally understood that a high elastic limit adds nothing to the stiffness or rigidity of a part It does add to resistance to fatigue but with the case in point the shaft is over size and fatigue cannot take place in the absence of bending

The same general condition applies to gears of all kinds It is not the rule, by any means, that gears of smallest section are made of the strongest steels. This should be so and is so in one very marked case On the other hand many very heavy gear sets, duty considered contain steel of greatest strength and all out of proportion to necessity This is unreasonable as it is obvious that strength should be a function of design. A bridge or a building is calculated to a nicety as yet automobiles rarely are Knowledge of steel is not yet sufficiently wide-spread The history of the automobile is short and there has not been time enough to disseminate knowledge of so many special steels and special treatment Then too an air of mystery regarding special steels and secret treatments has been fostered in some circles in such a way as to befog the issue and retard the spread of truth.

This paper treats of the various kinds of alloy steels and their applications in the automobile industry Attention is called to the necessity of selecting steels which will do most efficiently the particular work for which they are intended.

At the beginning of the automobile art the steel industry was old Alloys and heat treatments were no mysteries to the steel metallurgist Makers of armor plate gun tubes propeller shafts and other important specialties had been using many grades of steel and many treatments to meet peculiar needs. This knowledge had not and does not spread readily to makers of small arms sewing machines, bicycles or typewriters and they all need it to some extent

Some reason for this is found in the "old fashioned" selling methods of many steel companies Most salesmen are not furnished with accurate knowledge of the steels they sell or if they are they are forbidden to use such knowledge on possible customers They use a line of argument that contains no metallurgical information and is too often far from the truth There are large numbers constantly engaged in this way so it is no wonder that little real progress is made by aid of the salesman Fancy names and fancy prices for common steel is their specialty

It is a pleasure to feel that such methods are giving way to others and better The steel works engineer metallurgist or chemist is now placed in contact with the consumer His wants are learned and supplied without secrecy or mystery The opportunities of change and improvement are pointed out and advance in the art will be rapid As it is now there is but little knowledge among consumers as to the relative importance of analysis and heat treatment or of the importance of casting rolling hammering and cold working of steels Consequently many consumers are in doubt as to what to believe the truth as expounded by the conservative metallurgist or the near truths about the special alloys of the salesman

Before taking up the finer steels it is well to study the history of what preceded them in the automobile art

At the outset carbon steels were mostly considered and known as machine steel Such steel was available and cheap or at least low in first cost Such steel is not always cheap as much of it tends in machining to such an extent that work is ruined or will not permit the cutting of a thread at all because of its softness Such machine steel is of about the following composition It is not strictly speaking machine steel but there is so much of it on the market so called, that it must be recognized Carbon 0 08 to 0 13 per cent phosphorus 0 08 to 0 10 per cent manganese 0 40 to 0 60 per cent and sulphur 0 06 to 0 08 per cent

Machine steel, so called as found in steel warehouses is not all alike by any means This lack of uniformity is discovered by the user whose judgment usually is that the steel is no good anyway and does not behave twice alike in the machine shop

The best machine steel then existing in stock was of about the following composition with carbon from 0 18 to 0 25 per cent with other elements like the foregoing analysis Such steel machines smoothly and cuts a keen thread A slight increase in carbon coupled with the other elements given makes a very marked difference in machining quality A third quality of machine steel found on the market at the time in question was between the other two in carbon contents and much higher in manganese analyzing about as follows: carbon 0 12 to 0 18 per cent phosphorus and sulphur about 0 08 per cent and manganese from 0 60 to 0 90 per cent The manganese contents made for smooth cutting and the steel was a good one for carriage axles which must be machined very rapidly and other similar uses

These machine steels were all characteristic of Bessemer output and were put into the early automobiles They answered the purpose until the machines began to wear fairly well and poor (weak) design developed High carbons were tried and wrought iron was tried all in a blind unreasoning way Some troubles were cured but some could not be cured by any change of material known at the time The details of design were such as to cause failure with any material Failure was delayed but not prevented

One grade of steel common then and now, known as screw stock deserves notice as it plays a more important part in automobile construction that it ought to It is close to machine steel and is sometimes sold as such. The approximate analysis is as follows: carbon 0 08 to 0 12 per cent., phosphorus 0 12 to 0 18 per cent., manganese about 0.50 per cent, sulphur about 0 10 per cent The dominant element that makes for easy cutting is phosphorus, which is twice normal for Bessemer steel. More steel of this quality than of any other composition, can be put through an automatic screw machine in a given time, and turn out a fine product. But the drawback is phosphorus, which causes brittleness in steel and makes it unsafe for automobile construction. Except in screws of no importance or parts carrying no load, it should not be used. Important screws are now made of alloy steels heat-treated. Connecting-rod and engine-base screws for example The above screw stock after casehardening, as it often is, shows a coarse brittle grain even with the best of treatment No hardened parts of this quality should be used.

At the present time little steel high in phosphorus finds its way into automobile construction Basic Open Hearth steel is mostly used and this is uniformly below 0 04 per cent in both phosphorus and sulphur

This quality of steel in the vicinity of 0 10 per cent carbon machines with the greatest difficulty, consequently a standard machine steel has been developed containing enough carbon and manganese to offset the softness. The analysis is as follows: carbon 0 20 to 0.30 per cent., phosphorus and sulphur not over 0 04 per cent., manganese 0 40 to 0 70 per cent

This quality of machine steel handles well in every stage of manufacture and responds to heat treatment in a way that makes the product suitable for many parts of a car This steel is a fine steel for general run of drop forgings It is suited for the important members of low priced light cars and for carbonized and hardened bevel and transmission gears in such cars as are of low power and generous gear design

With the general use of basic open hearth steel this type of machine steel is bound to be generally adopted Its usefulness is very wide spread and its cost as low as any open hearth steel The extra expense that is warranted is the care necessary to free from seams or other physical defects This is done by the steel maker or the one who prepares the billets or bars for shipment. Freedom from seams insures a sound product at the finish of an expensive series of operations and is worth paying for

Simple heat treatment will give an elastic limit per sq inch of 60 000 lbs This is the result of quenching at about 1,500 deg F in oil, then partially annealing at 800 deg or 900 deg F Such strength is accompanied by good refinement of grain and corresponding toughness and capacity to resist shock and repeated alternate stress The machine steels previously mentioned would not be safe under the foregoing treatment or any other; as refinement of grain does not take place to a satisfactory extent in the presence of so large a percentage of impurities

Without a fine grain development in steel fatigue takes place very rapidly In using this term "fatigue" the same phenomenon is in mind that is often referred to as crystallization Cold crystallization does not take place It is a different physical change and will be discussed later

About the years 1893-1894 bicycle parts often failed (to quote) while riding along the smoothest road The fractures did not exhibit coarse crystals as a rule particularly in cold drawn spoke wire or tubing But in every case there did exist an opportunity for concentration of strains bending or vibration at a limited section These failures led to studies of fatigue conditions

It was commonly thought by well trained mechanics that the softest toughest steels would resist longest under these conditions simply because of the tough quality This was found to be not so Tough and soft steel is weak steel having an elastic limit per sq inch from 30 000 to 40 000 lbs A good grade of 0 40 per cent carbon steel may have an elastic limit of 50 000 or 60 000 lbs Such steels in an annealed condition were compared under such circumstances as to produce a fatigue break The dead or actual load used in comparison was the same This load was chosen to produce a fiber stress nearly as great as the elastic limit of the weaker steel say 25 000 lbs per sq inch (about 84 per cent) This stress was only 50 per cent of the elastic limit of the stronger steel The weaker steel soft and tough, broke quickly after 20 000 to 50 000 alternations of stress The stronger steel looked upon as being brittle and hard endured say 400,000 alternations of stress, an increase not in direct proportion to strength and quite contrary to the characteristic of toughness as measured by elongation It is evident that the toughness was not the controlling element under fatigue conditions and that strength as indicated by elastic limit was an important factor with some other element not obvious, playing an important role Such an element was sought in the crystalline structure Such structure is fairly indicated by transverse fracture for the purpose in hand The fracture of the low-carbon tough steel is coarse grained with crystals presenting large cleavage planes. That of the higher carbon, brittle steel, showed a close grained structure with no crystals having cleavage planes of conspicuous size. That is, the steel that endured longer was strong and fine grained These were the controlling elements.

It is for this object that all heat treating processes are practised—to produce greater strength and to refine the grain The most reasonable steel to use in automobiles is that which will respond best to treatment or that will respond sufficiently for a given purpose, dimensions and duty considered There is no reason in selecting a steel that will not respond somewhere in proportion to the cost of the operation; that is, the improvement must be material. Neither is it reasonable to select a steel at great cost that will respond to such an extent as to be way beyond the necessities of the case.

The treatment necessary to give a steel depends some-

what upon the physical condition of the steel as received by the consumer or user For example, it is quite possible and often happens that bars of steel reach the manufacturer of automobile parts in a very coarsely crystallized state, this being due to the last forging or hammering operation prior to shipment by the steel mill. If this steel is to be used by the parts maker without further drop forging or other heating operations, the steel must receive a thorough annealing In the absence of such annealing operation, which will reduce the coarse condition of it to a properly refined condition, a single heat treatment will not produce the expected results

If, on the other hand, the bar or billet is to be forged, then this coarse crystalline condition matters but little and the annealing must necessarily follow the forging operation and for the same reason, to guard against a possible condition of coarse crystallization which will not be refined by a single heat treatment

Our steel makers would do well to learn whether or not the consumer of the steel is to again forge. If not, annealing should be the final operation at the steel works in all cases Otherwise, steel of good quality may not perform as well as it should

It is not always possible for the steel manufacturer to know whether or not steel is to be forged again and, in view of that fact, it is the habitual practice of some of the steel mills to anneal as a final operation No harm is done if the steel is again forged, and if not forged the steel is found, by the user, to be uniform in machining qualities and well behaved under heat treatment Uniformity of machining quality is of far more importance in the eyes of the mechanic than is fully appreciated by many steel companies Many thoroughly good qualities and shipments of steels are complained of and perhaps condemned because of the presence of so called hard spots and bad cutting qualities The machine shop cannot be expected to know that it is not the composition of the steel that is at fault and the steel maker should guard against such complaints by the relatively inexpensive operation of annealing

These remarks apply very strongly to tool steels that are to be shaped into expensive tools, to spring steels and to the higher carbon steels in general They apply in a lesser degree to the lower carbon steels but nevertheless are of great importance

Many machine steels are condemned because tools are rapidly dulled in machining them and the complaint is as a rule that they are too hard to cut As a matter of fact they are too soft to cut smoothly They tear and cling to the point or edge of a tool and the cutting operation becomes more or less of a rubbing operation which creates heat and dulls the tool by softening it Proper annealing suited to the carbon will correct this fault, but the machine shop manager cannot be expected to know this and probably has no facilities for annealing or other heat treatments in many cases

Take an engine crank for example Other considerations than strength influence the design It must have ample diameter to furnish adequate bearing surfaces It must be rigid and stiff No alloy can increase this latter quality A steel with 60 000 lbs elastic limit per sq inch is quite strong enough to outlast the engine One of 200 000 lbs elastic limit would make no better crank shaft under the assumed conditions and would cost more at first cost in forge in machine shop and in heat treatment This is a fair example of unreasonable use of alloy steel

To return to qualities producing endurance under alternate stress A drop forging as it comes from the dies is likely to be in a non homogeneous condition as the result of the process and at the best, because finished at a relatively high temperature is likely to possess a very coarse open grain If intended for a vital part this grain must be refined It may be perfectly done by proper heat treatment and it is done habitually by careful operators The result is a homogeneous piece of metal No other character of steel is fit to enter the construction of an automobile where it is potentially possible of much harm or much good Carbon steels should be so treated alloy steels must be if fair value for money spent is to be received

Alloy steels of expensive variety have been put into cars without heat treatment just to say that they were used An alloy steel not suitably treated, that is in an annealed or forged state, is little if any better than good open hearth machine steel in an annealed condition Its endurance under fatigue test is low Its elastic limit is low, and its structure as indicated by transverse fracture is bad Such use of alloy steel is unreasonable and the only additional value obtained for the excess paid as compared with carbon steel is an advertising value.

On the other hand alloy steels suitably chosen and heat treated have extricated many an engineer from real trouble A driving shaft, having 60,000 lbs elastic limit, for example, may have proven weak with good carbon steel Because of the design of connecting parts a change in dimensions is often practically impossible. A solution is easy with a good 0 30 carbon, 3 5 per cent nickel steel treated to 90,000 lbs. per sq inch elastic limit, or if necessary a chrome-nickel of high carbon treated to 150,000 lbs. elastic limit Such applications of alloys are worth all they cost and are reasonable in every way

It is the alloy steel that responds best of all steels to heat treatment. Results are obtainable that are nothing short of wonderful. Only recently a tensile strength of 300,000 lbs. per sq. inch has been reached. Coupled with such strength, say 300,000 lbs. per sq. inch, very great ductility is obtainable as indicated by elongation and reduction of area at section of rupture Too great stress cannot be laid on this last item It is the best measure, in a tensile test, of the degree of refinement of grain attained by heat treatment. Reduction of area will be slight if the crystals or grains are large If the grains are large as already stated, endurance under fatigue will be little and endurance is beyond argument the most valuable asset of an automobile subject as it is to *shock and vibration at all times, while in motion*, and to an extent beyond any other mechanism

Attention has been called to the relative endurance of 0 10 and 0 40 per cent carbon steels under fatigue test Under the same dead load a specimen of 0 30 per cent carbon, 3 5 per cent nickel heat treated will endure several million alternations of a 25,000 lbs per sq inch fiber stress, and a specimen of 7.5 per cent nickel has endured one hundred million without rupture with the fiber stress at about 30 000 lbs per sq inch The tensile tests give no indication of any such difference in endurance unless it be in the reduction of area coupled with a high elastic limit These figures are always large with good endurance The reduction of area is a measure of fine grain, so it would seem that this quality may be the most influential in determining endurance

There is a good chance for theorizing and reasoning along this line With the theory of cold crystallization set aside, a reasonable cause for breakage must be found Steel may be considered as made up of crystals *which interlace and adhere* If a test specimen were made up of crystals whose faces equalled the diameter of the specimen, there would be the exaggerated condition of all adhesion and no interlacing One cleavage plane extending across the specimen It is easy to conceive that the separation of surfaces once started would jump at once across the specimen and rupture would occur There would be only adhesion to overcome It is equally plain that were the same specimens made up of an infinite number of crystals, that a separation started at the periphery would meet with an interruption before being of finite size after which a fresh start might recur at another point to meet with similar interruption In this way an infinite number of starts would be necessary to bring about rupture In other words there would be no chance for a continuous fracture along any one line or surface and rupture would be delayed indefinitely

A fibered piece of steel endures better than one not fibered although both may be of very fine grain It is easy to conceive that if fiber is all the name implies that an incipient fracture formed in one fiber could not continue across the space between fibers and would thus stop Wrought iron breaks under fatigue as in an axle or shaft The fracture always shows crystals Is it not possible that a fatigue break can take place only where crystals exist and that because crystals are at a given section fracture takes place there?

It is easy to understand how a progressive fracture may proceed along the faces of a series of crystals as in the splitting of granite by means of wedges driven into a row of holes It is not easy to conceive the splitting of good fibrous hickory or elm except with and along the fiber Splitting across the fiber is impossible there could be no continuous fracture and therefore no rupture

A fatigue break has been described as progressive intermolecular rupture It would seem more probable to be intercrystalline inasmuch as the molecules of a given composition are doubtless all of a size regardless of heat treatment or physical treatment On this theory heat treatment would cause no difference in behavior under fatigue which would be contrary to fact

Another phase of fatigue is that such breaks rarely if ever occur unless strains concentrate at or near one plane or section If strains be distributed as in a beam of uniform strength fatigue does not occur A generous fillet or a taper retards fatigue almost indefinitely A sharp corner causes it to occur very quickly

Design and material both play an important part and the two must be considered simultaneously if good engineering is to be attained If a design be adequate with poor material it is folly to buy better If design be suited for the best then only such may be used otherwise bending and breaking will occur at once These statements seem too simple for reiteration but it is a sad fact that both simple truths are violated in automobile construction

There is one form of heat treatment as old as the hills that is little understood by many that have practised it longest namely casehardening" It is easy to turn out coarse or fine grained product The fine grained is desirable (as in good tool steel) the coarse grain is not, as in burned tool steel Too few realize that a low grade steel after carbonizing is no longer low grade It has had money spent on it to improve it and if the low carbon was pure steel the high carbon exterior the result of carbonizing is pure high carbon steel, therefore good tool steel and must be treated accordingly

No tool dresser would heat tool steel in boxes for ten hours at a temperature of 1 700 deg F then quench in water at that temperature and expect a tool to do good work Yet this is exactly what is done in many otherwise well regulated plants, and the steel is blamed if the parts so treated are brittle. So treated the crystals are large, the steel is brittle

If used for ball or roller bearings, the polished surface is friable and crystals spawl out thus starting pits and fractures Suitable refining treatment improves this condition and makes a success out of a possible failure.

In casehardened parts two qualities of metal are to be dealt with, and the best practice demands treatment that will refine both grades The interior of two are the original carbon and the exterior a carbonised layer of a higher carbon The refining temperature of the lower carbon is higher and one treatment must reach this. The other temperature, correct for the high carbon, will not undo the refinement of the lower carbon. Thus by two treatments both qualities are fully refined and the composite structure is a good one. Alloy steels are subject to the same laws, and it is only necessary to be acquainted with the critical points of the various compositions to get the best results

Transmission gears and main drive bevel gears are successfully made of carbonized steel, both carbon and alloy The quality selected must be referred to design and duty The duty of constant mesh gears running in oil is relatively easy if the dimensions be generous The duty of clashing transmission gears is never easy and may be awful with [illegible] manipulation by the car driver and with clashing taking place under loaded or partially loaded conditions

With equally good design the bevel driving gears do not need the same or as good steel as the transmission gears It is common and good practice to make the large bevel gear of good carbon steel and the driving pinion meshing with it of an alloy steel

The character of the treatment and resulting condition of the steel is of vastly more importance than the composition of the steel used The best of alloy steel may be so handled in treating as to produce a weak and inferior part Similarly by the best of treatment good open hearth machine steel may be so well handled as to make a most excellent main drive pinion or other part

It is true that the best must be produced for a few designs but such are much in the minority at this time There has been very little real close designing as yet Empirical knowledge and data as to available materials are not yet exact The art of heat treating is not uniform and wide spread among producers of automobile parts A liberal margin of safety against uncertainty and non uniformity is still the rule

There is one practice in vogue among purchasers of alloy steels that does not seem to be founded on good reason It is that physical requirements are specified in face of the fact that the steel is to be forged and heat treated before being used in a car Its final condition may bear no relation to its purchased condition It may be carbonized for example If steel be purchased on chemical analysis, the control is sufficient With a known composition heat treatment may be intelligently directed without reference to original tension test characteristics

If to be used as purchased the matter is different and physical characteristics must be known Elastic limit reduction of area elongation and tensile strength in the order named are desirable If these physical tests be demanded then complete chemical analysis must not be The steel manufacturer cannot produce if tied hand and foot It is proper to specify chemical analysis as to impurity that is phosphorus and sulphur and also as to the dominant elements nickel chrome nickel and so on Even in these elements manufacturing tolerances must be allowed The practice of limiting all elements coupled with physical requirements is wrong and often leads to the absurd situation of specifying an impossibility

Even at the best with the one writing the specifications knowing exactly what has been the practice in one steel works it is not certain that in another works the result would be quite the same Some works use melting processes, casting methods and forging methods that may easily modify physical characteristics as compared with practices in other works

With a given quality of automobile in view the number of grades of steel necessary to construct it is few namely a good all around forging steel, a steel of slightly better quality to be used for gears a spring steel and a steel suited for the pressed sheet steel portions of it

These steels properly handled and heat treated each part for its peculiar duty will produce a car of very high grade so far as the steel portions are concerned

The car of extreme design racing or otherwise one that has been designed to strip off the last pound of weight must be handled differently Such a car is the exception and must be treated accordingly

If an order be accepted at all under such unfair restrictions it must be at an advanced price to cover probable difficulties This simple fact is so well known to the steel producer that it is apparently [illegible] it but it is not well known by the steel consumer and needs repeating for their benefit

To sum up the attempt has been made to indicate that *alloy steel is better than plain carbon steel* that is stronger and more enduring that the design of some cars is such as to necessitate the use of the strongest alloy steel and that the design of others is such that an alloy steel is superfluous and money wasted

That steel that is good for one purpose is bad for another and really that the term good steel is meaningless unless it be understood "for what" Pure steel meaning freedom from impurities, means something always It insures that such steel will give "good results if the composition is suitable for a purpose and if the steel be treated to develop proper physical characteristics for the duty to be performed Several steels (compositions) may be available that will perform a given function perfectly if properly selected and treated No consumer need be tied to one maker one composition nor one method of treatment Several of each are always at hand that will give satisfaction Reasonable use of steels can only be reached along lines as broad as this — *Journal of the Franklin Institute*

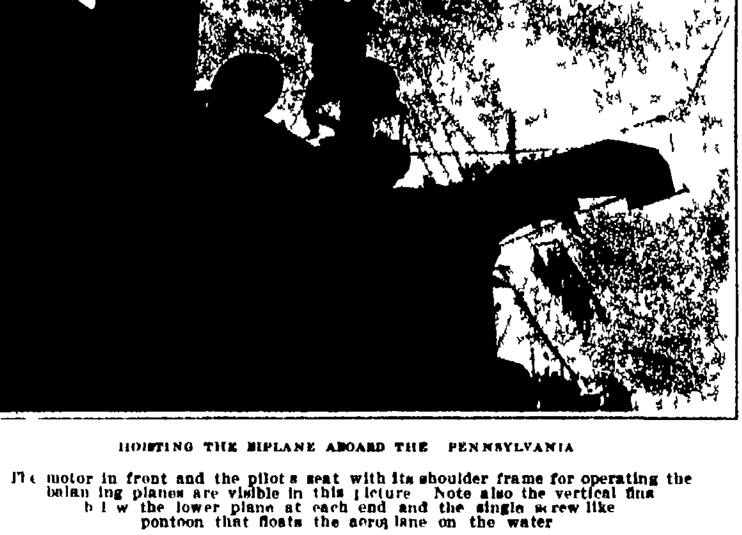
A British inventor has devised a new standard resistance unit for heavy currents It consists of a glass tube filled with mercury and fitted with platinum terminals communicating with the mercury The heat produced by a current passing through the mercury causes the latter to expand and rise in an auxiliary tube of fine bore, graduated in ohms.

Curtiss's Experiments in Rising from the Water

How the Winner of the Scientific American Trophy Developed a Satisfactory Float for His Biplane

During the past two years Glenn H Curtiss, who, *more than any other experimenter has been given to* developing the aeroplane for various uses, has experimented with floats for his biplane that would enable it to rise from the surface of the water Something over a year ago he succeeded in developing a speed of about 20 miles an hour on the water but this was insufficient to rise from the surface

At the first try-out, while traveling over the water at high speed Mr Curtiss found himself suddenly nearing the shore, and to avoid running aground he turned his horizontal rudder sharply upward, with the result that the machine rose from the water with perfect ease He soon alighted again, and in the second flight he made a circle and remained in the air a minute and 21 seconds. Two other experimental flights were made the first day, and on January 27th he made a 3½ minute flight and stated upon alighting that he found no difficulty in remaining aloft as long as he pleased The machine showed a speed of 50 miles an hour in the air as against 45 miles an hour when skimming over the surface of the water



HOISTING THE BIPLANE ABOARD THE PENNSYLVANIA

The motor in front and the pilot's seat with its shoulder frame for operating the balancing planes are visible in this picture Note also the vertical fins below the lower plane at each end and the single screw like pontoon that floats the aeroplane on the water

At the beginning of the new year Mr Curtiss moved to the Pacific Coast and set about endeavoring to develop suitable floats which would make it possible for his machine to rise from the surface of the water These experiments have been carried on at San Diego where Mr Curtiss is instructing several naval and military officers in the art of flying

In his first experiments on the Pacific Coast Mr Curtiss followed the successful experiments of this sort made by M Henri Fabre at Marseilles France about a year ago as far as the design of his floats was concerned He constructed one large float six feet wide five feet from front to rear and one foot thick at its central point, and placed this under the center of the machine The bottom of this float was perfectly flat and arranged at an incline of 10 or 12 degrees Some distance forward of the main float, at about the position of the front wheel in the land machine, another float six feet wide by one foot from front to rear and six inches deep was placed; while at the extreme front end of the machine on a special outrigger was mounted a small elevating hydroplane six feet wide by eight inches in a fore and aft direction, and one and one half inches thick. This hydroplane was fixed at an angle of about 25 degrees and was intended to lift the front part of the machine A spray shield was fitted back of it as shown in the diagram

The first experiments were made with these new floats on January 26th last; and although they made a considerable disturbance in the water especially at low speed, the aviator was enabled to get up a speed on the surface of about 45 miles an hour He found that at as low a rate as ten miles the hydroplanes (which normally were submerged) rose to the surface while as the

Not satisfied with the several floats with which he had attained his first success in rising from the water Mr Curtiss immediately constructed a single float 12 feet long by 2 feet in width and 12 inches deep This float is built of wood and resembles a flat bottomed boat or scow the top being covered with canvas to keep the water from getting in Three feet from the front end the bottom is curved upward forming a bow the full width of the float while at the same distance from the rear the float slants downward in a similar manner

This single float is placed under the aeroplane in such a position that the main weight of the machine and aviator is slightly to the rear of the center of the float which causes the latter to incline upward slightly and thus gives the necessary angle for hydroplaning on the surface of the water The weight of this new float is but 50 pounds, or less than half as much as that of the two floats that were used before

The paint was barely dry on the new float before Mr Curtiss had it fitted to his machine and gave it a trial This was done on February 1st and the trial was thoroughly successful The machine ran over the surface of the water with very much less disturbance than before and rose in the air readily A glance at the photographs showing the new and the old floats in action will give one an excellent idea of the much less commotion caused by the single scow shaped float Besides being much more compact and creating less disturbance this

the surface, even though the scow-shaped float used is but two feet in width.

After meeting with success with his new float, Mr Curtiss, on February 17th, made more flights with the motor and propeller placed at the front of his biplane and with his seat placed at the rear of the main planes. The chief of these flights was one which he made from North Island, where he is experimenting, over San Diego harbor to the cruiser "Pennsylvania." He alighted upon the surface close beside the cruiser and his aeroplane was hauled up beside the warship and placed on her deck. Two of our illustrations show the improved machine skimming the surface and Mr Curtiss landing on the cruiser In the latter picture an excellent idea of the biplane and float is obtained. The special twin V-finned tail with a vertical fin in the center, and the stabilizing fins running from the lower plane to the inclined props above mentioned, are shown distinctly in this picture, as well as the balancing planes at the rear of the main planes half way between them, and the scow shaped float beneath The reversed positions of the motor and aviator's seat is also apparent, but the greatest change is the removal of the front horizontal rudder For this reason it was possible to raise the machine so close alongside of the cruiser that the aviator could climb aboard It would seem that this new arrangement of motor and propeller and the doing away with the front rudder was very good for naval work, although Mr Curtiss himself did not like the arrangement on account of the air from the propeller striking his face and the motor and propeller interfering with his view forward

After a short visit on the cruiser the aviator was again lowered to the surface in his machine A sailor started the engine, and Mr Curtiss flew back to his starting point in short order The naval authorities were greatly pleased with his demonstration and it is probable that the Navy Department will purchase one of these machines in the near future and continue the instruction of its officers

After increasing the surface of his biplane Mr Curtiss on February 24th, took up one of his naval pupils, Lieut T G Ellyson, as a passenger He made a flight of 1½ miles, rising to a height of 100 feet and flying as slowly as 25 miles an hour or as fast as 50 miles an hour, at will Lieut. Ellyson was seated on the pontoon below the aeroplane He could look down in the water and see bottom at a depth of 25 feet, and he believes submarines can be easily located by flying over the water The slow speed at which it is possible to fly will make the biplane especially useful for bomb dropping As we go to press Mr Curtiss is about to try his machine fitted with wheels and floats as well

SKIMMING THE SURFACE AT 40 MILES AN HOUR WITH SCOW PONTOON

The water remains nearly unruffled as the craft passes over it. Note disturbance caused by the floats compared with that caused by the scow

THE FIRST FLIGHT OF A BIPLANE FROM WATER.

speed increased only the rear edges of the two main planes were required to support the machine The aeroplane readily attained sufficient speed to rise in the air, for as the speed increased and the floats emerged from the water, the head resistance of the floats diminished and there was only the skin friction of the water on a few inches of the rear edge of these floats, plus the air resistance, to be overcome.

float or scow can be used for carrying articles or a passenger

In order to keep the aeroplane from tilting to one side or the other, an inclined stick four feet long and three inches wide, to which is attached on its upper side an inflated rubber tube, is fastened to the front edge of the lower plane at each end. By the use of these props the aeroplane does not tip readily when skimming along

Problems in Chemical Industry*

By J T Baker

[The writer discusses the difficulties which arise when an attempt is made to apply on a commercial scale the results obtained from laboratory experiments. He is of the opinion that the chemist is best fitted to overcome these difficulties who combines with the scientific mind a certain amount of common sense]

Industrial chemists may well pride themselves upon being engaged in one of the most important and useful branches of the so-called sciences of the present day, and one that requires, in a certain sense, more science in the solution of its problems, than any other

The question has often occurred to me, however, to what extent is chemistry a science and is the solution of its problems a purely scientific work After analyzing the subject carefully, I am led to venture the statement that chemistry, as we understand it is not a science in the strict sense of the term, although it cannot be denied that the enormous advance that has been made in the field of chemistry during the past century, is due in a measure at least, to what is known as scientific investigation and the application of scientific principles. Much of the success, however, if not the largest part of it, is due to the application of what is known as common sense, in contradistinction to so-called science.

Some one has defined science as "organized common sense," and this definition, to a certain extent, is true, but the common sense that I refer to is that which is, so to

*The Journal of the Franklin Institute.

speak, unorganized, and follows no given rule, but occasionally arrives at a conclusion in a problem, without any definite reason, except it be on the plea, that all great discoveries are the result of accident.

Taking the definition of science as organized common sense, or to use another expression, as systematised facts, this definition also implies the further use of knowledge thus systematised, and the distinction between a scientific and an unscientific mind, is that the former adheres to a system and applies it, or attempts to apply it to various problems, while the unscientific mind follows no definite line of action, and arrives at results by accident or by good luck at guessing

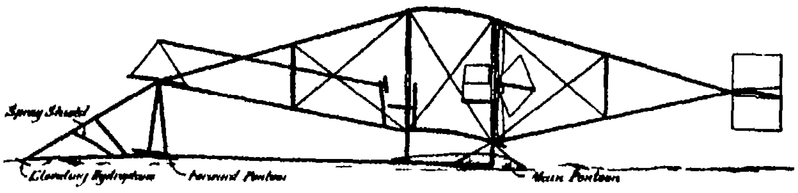

DIAGRAM SHOWING ARRANGEMENT OF HYDROPLANE FLOATS.

On the basis of the above definition of the term science and what it implies, it is evident that the most perfect science will be that in which the systematising of facts is most complete, and the degree of perfection will be determined by the extent to which the system can be applied and followed A perfect system is one that is based on a well-defined principle, in which every step is an application of this principle In this respect it will be found that mathematics is the most perfect system, for here the system is so perfect that its principle can be applied and followed to an unlimited extent. The conclusions reached are absolute and hold good for all time and under all conditions This is pure mathematics and it is pure science

In the applied sciences however, the systematising of facts is not so complete, and in consequence the systems are not perfect, and can therefore be followed only to a limited extent. The avowed principle of the system and the conclusions reached do not agree, although in some cases the disagreement may be so slight as to be insignificant Mathematical astronomy affords an example of the most perfect system of applied science for here while the systematizing of facts is not absolutely perfect, and consequently the conclusions are not absolute they are so nearly perfect that the conclusions reached may hold good for thousands of years to come The variations may be so slight as to be almost infinitesimal, but as long as the conclusions are not absolute, the system is not perfect In the final analysis the scientific mind fails, and the problem is solved by the unscientific mind, which makes a guess at the result by striking an average

The absoluteness of pure mathematics as a pure science, and the approximate absoluteness of the science of astronomy, may be explained by the fact that one factor only is taken into consideration in mathematics, namely, that of the relation between objects expressed in symbols, the physical properties of which are entirely ignored while in astronomy, it is the relation between planetary bodies, the physical and chemical properties of which, however much they may affect the final results, are also practically, if not entirely, ignored

In fact, as we proceed to explain science in general on this basis, and apply the explanation to the so-called sciences that involve factors whose physical properties must be taken into consideration, it will be found as the number of factors increases, that the systematising process becomes more difficult and impossible, while the purity and accuracy of the science decreases accordingly This will be observed as we pass from astronomy, where the factor is only one, or practically one, to mechanics, physics, chemistry, geology, biology, psychology, etc., the factors of which increase, while their accuracy as sciences decreases in the order named, until we reach sociology and theology, where the factors, consisting entirely of the vagaries of the human mind, become so numerous and antagonistic that any systematising whatever is practically impossible, and to these the term science has consequently no application.

It will thus be seen that the term science when applied to the various concrete sciences, has a very limited application, depending upon the number and complexity of the factors involved, and the pursuit of any of the so-called sciences in which the factors become numerous, would soon come to a stand-still, if it did not include the assistance of the unscientific mind; because a multiplicity of factors gives rise to problems, the solution of which is accomplished not so much by science as by empiricism. The tendency of the scientific mind, trained as it is, to look at problems along well-defined lines, in obedience to some system or law, is to ignore conditions and suggestions that do not seem to conform to these laws, with the result that valuable facts are often overlooked The tendency of the unscientific or practical mind is to go to the other extreme, and ignore laws and systems, and try any suggestion that chances to come along, with the result that while much valuable time and labor may be lost, the loss is fully compensated by a few valuable successes

I think it is safe to say that it is to the unscientific or practical mind that we are indebted for discoveries in the field of science, for it is only as we deviate from the well known and familiar paths laid down by the scientific mind that we stumble upon and discover new facts, and while the unscientific mind stands astonished and at a loss to know what to do with the discovery, it remains for the scientific mind to lay hold of the novelty and find a place for it in some general system of things It has been said that the difference between a discoverer and an inventor is that the discoverer is one who uncovers some new thing which he cannot make use of for lack of knowledge while the inventor is one who takes the novelty and by use of his accumulated knowledge, is able to recognise and make use of it by means of a so-called invention

REAR VIEW SHOWING MAIN HYDROPLANE FLOAT USED IN FIRST EXPERIMENT

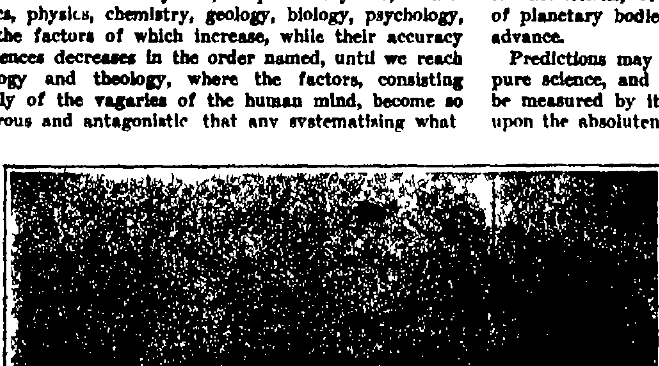
While science may be defined as the systematizing of facts, the ultimate object of the system is to arrive at or assume, if necessary, some law that will not only satisfactorily explain the facts, but will also enable us to deduce from the law new facts, or in other words to predict new facts or events Pure mathematics affords the best example of this ability to predict or make deductions, for its deductions are without limit Mathematical astronomy affords the next best example, for its deductions, or predictions, relating to the position of planetary bodies, can be made thousands of years in advance.

Predictions may therefore be considered a criterion of pure science, and the purity of a so-called science may be measured by its ability to predict, and this depends upon the absoluteness of the law or principle upon which the predictions or deductions are made, for where there is more than one principle involved, the deductions must be more or less antagonistic. In pure mathematics there is but one law or principle—"The whole equals the sum of its parts," and although there may be many corollaries to this law, the deductions are absolute and there can be no antagonism In astronomy also, there is practically but one law or principle, the law of gravitation, expressed in mathematical terms, and the deductions or predictions therefrom are almost, if not quite absolute The absoluteness of a principle implies absolute consistency of its application, for any deviation therefrom must necessarily involve the application of other principles. Pure science therefore is a system that involves an absolute principle and absolute consistency in its application

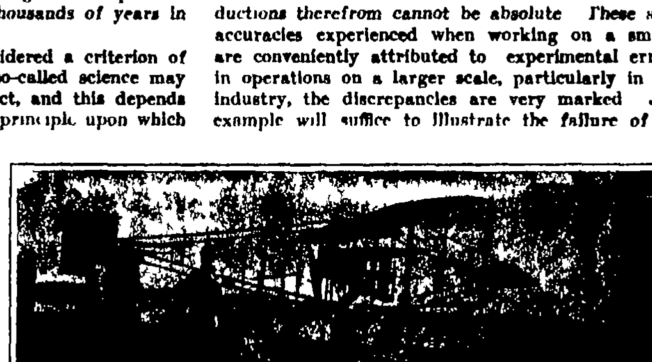
Now with this understanding of what constitutes pure science, let us turn to the so-called science of chemistry —does it involve but one law or principle, and do we or can we consistently apply this law to the various problems encountered?

Up to the time of Dalton it is well known that the study of chemistry was in a more or less chaotic condition, but after Dalton annunciated his so-called "Atomic Theory," and the same was generally accepted as a working basis, if not as a fundamental law of nature, chemistry became known as a science Why? Because here was a fundamental law or principle that was considered absolute, and could be consistently applied with the result that absolute deductions could be made upon the strength of it, and new facts or events could be predicted Thus we can predict that if the atomic proportions of Cl and H are as 35 to 1, then 35 parts of Cl combined with 1 part of H will produce 36 parts of HCl whether we take grains, pounds or tons of the materials We can predict that whatever quantities we can combine in chemical affinity we shall find the same quantities in the resulting compound and in doing so we have predicted a new fact or law known as the law of the "Conservation of Matter" By a combination of various laws deduced from the fundamental law, we get the law known as the Periodic Law," from which we can predict new and heretofore unknown elements

In so far therefore as the law of the Atomic Theory is applied in making deductions therefrom, and in predicting new facts to that extent, we may honestly say that chemistry is a pure science But in chemical investigation in research work, and in chemical industry, etc do we or can we apply this law to existing conditions and to the problems that confront us? Working on a small scale, where the only object is the demonstration of the law the application may so closely approximate the law as to warrant us in saying, on the basis of probability, that the law is applicable, but when the law is applied on a larger scale, as must be the case in chemical industry its limitations become very apparent. It would be difficult if not impossible to mention a single instance, where it is not necessary to alter calculations based upon deductions from the law, in order to obtain satisfactory results Even the atomic weights, upon the application of which the law is based, are not absolute and it is therefore self-evident that any deductions therefrom cannot be absolute These slight inaccuracies experienced when working on a small scale are conveniently attributed to experimental error" but in operations on a larger scale, particularly in chemical industry, the discrepancies are very marked Just one example will suffice to illustrate the failure of the law in its application—the manufacture of HNO_3 for instance. The law would require the combination of 179 parts of $NaNO_3$ with 98 parts of H_2SO_4, and on a very small scale in the laboratory these proportions might give results approximately accurate, but on a large scale using cwts. or tons, these proportions will not give accurate results by any means. That is not to say that the combination takes place in any other proportions



CURTISS IN FLIGHT AFTER RISING FROM THE WATER.



SIDE VIEW OF AEROPLANE SHOWING SINGLE PONTOON

THE FIRST FLIGHT OF A BIPLANE FROM WATER.

than those laid down in the law but that the proportions required to produce the calculated results, are not the same Here the deductions of the scientific mind fail and the unscientific minds steps in and by experimenting and guessing finally discovers that 95 parts of $NaNO$ instead of 172 must be combined with 98 parts of H_2SO to produce satisfactory results The proportions thus determined upon may then be accepted to a certain extent, as a working basis for the use of the so called scientific mind in working out future problems of a similar character

Here we see an illustration of the fact above referred to that discoveries are made by the unscientific or practical mind while the scientific mind endeavors to systematize the discoveries and thereby formulate laws for future use Both qualities are generally combined in the same individual in varying degrees and are essential for success in any line of work for discoveries unless they can be formulated into some system from which we can make deductions are useless, while on the other hand deductions alone from a supposed unchangeable law would soon become obsolete by reason of its limitations which are eventually revealed by new discoveries. If we possessed a universal law deductions therefrom would be without limit and discoveries which are now made by accident would appear as a process of evolution This is the case with pure mathematics in which there are no discoveries for each new fact is the result of a process of deduction or evolution

The principle of mathematics however as it is generally understood is not a universal law and although it is universally applied in all scientific work it must be remembered that there are other factors that enter into all problems each of which involves separate and distinct principles producing in the end an anomalous condition for where more than one principle is involved there must necessarily cease to be a principle In pure science as for instance pure mathematics there is but one principle involved and its application to symbols that have no intrinsic value involves no complex condition but in the concrete sciences we have besides the mathematical factor other factors principally physical chemical mechanical, and economical to say nothing of the temperamental known as the "personal equation all of which render the condition very complex and the application of an absolute law unless it be universal impossible This is particularly the case in connection with our so-called science of chemistry for the application of its principles involves all of the above extraneous factors and although they may be reduced to a minimum by the use of delicately adjusted appliances in connection with investigation work they are always present to interfere with the complete application of the principle

The question therefore "Is chemistry a science? If we answer it on the basis of the definition of science as organized common sense by which we mean a system involving an absolute principle from which we can make absolute deduction must be answered in the negative for as we have seen our deductions at best are only approximate and in the most important branch of chemical work industrial chemistry its application is more or less a total failure While it may be true that chemistry acquires the distinction of being called a science after the acceptance of Dalton's atomic theory as a working basis it cannot be claimed that the enormous advance since made in the field of chemistry is due to the application of this theory since in practical work we do not actually apply it at all Advancement is due rather to the inspiration that this theory affords by establishing a definite goal towards which concerted action may be directed for it is concerted action and unity of purpose among workers along any particular line that produce results

That chemistry is not a pure science, does not, however, imply that it is to be deposed from its position of importance among other so-called sciences, for the same condition applies to them all with the result that we have no real science except pure mathematics. Pure mathematics, however, limited as it is to symbols only, would be useless if it had no application to concrete things in connection with the other so-called sciences, and as this application is not perfect, owing to other factors present we must conclude that there is no such thing as a perfect science defined as "organized common sense"

To escape from this apparent absurdity, we are compelled to change our definition of the term science, and devise a definition that will apply to existing conditions. Instead of defining science as "organized common sense," we might define it as practical common sense," or as Prof James might call it, pragmatic common sense, that is to say the sense that makes use of anything that works All sense is common sense and the so-called organized common sense or science is judged, not by the degree of perfection of its system however necessary perfection may be as a criterion of pure science but rather is it judged by practical considera tion by results

Human nature is practical if it is anything and a theory no matter how profound it may be, even if it be a theory of life has little interest for us if it is not practical When a new theory is propounded, our first question is not is the theory true, but, will it work will it deliver the goods If not we have no use for it We judge a theory or system or any line of work, solely by practical considerations and these practical considerations are not academic but humanistic not scholarly attainments but things that add to the happiness and comfort of mankind

Human nature looks for immediate returns and of all lines of work can there be found one that gives for labor expended more satisfactory returns than that which is included under the name of chemistry It is ostensibly based on a fundamental principle and although the results may not accord with the principle the results are nevertheless, approximately what we are looking for which is achievement and even if incomplete we are satisfied to call it a science If its field of operations were confined to purely scientific work where the only object is the relations between hypothetical atoms its usefulness would be so limited that its work would be no more productive of happiness than astronomy which deals with the far distant planets or the study of metaphysics that deals with things transcendental

In fact the field of operations open to chemistry is unlimited and there is no important line of practical work in which mankind is interested that is not in some way related to chemistry On the other hand the field of practical chemistry is not limited to so-called relations but includes within its applications many conditions that are not strictly speaking chemical at all but mechanical, physical geological biological and even psychological From a practical point of view we might say that chemistry is the science of all sciences for it seems to include them all in one great whole From determining the elements of the stars down to analyzing our foods from steel making to farming chemistry is an important factor without the assistance of which no industry can hope to succeed Consequently its problems which we started out to discuss are of a most varied character and their solution requires not only a knowledge of chemistry but a thorough knowledge of all the other concrete sciences combined and most of all an appreciation of the fact that success is counted not by the profoundness of a theory but by practical attainments Chemistry as a science is as simple in its operations as the multiplication table and involves no greater problems because its application is confined to symbols, that give rise to no counteracting conditions. Real problems arise when application is made to concrete things, that involve not only chemical conditions, but physical, mechanical, economical, temperamental, etc. Temperature, concentration, and so-called "mass action," form, size and construction of implements and utensils employed are all factors that must be harmonized and systematized, and this harmonizing process is what constitutes the problems of chemistry, problems that no scientific mind alone, much less, a purely chemical mind can solve. They are solved only by the broad, common sense, "pragmatic" mind, that is fortified with a knowledge of things in general, and often by the mind that boasts of no knowledge whatever, for as is sometimes the case, problems are solved by an ignorant mind, because unhampered and unprejudiced by preconceived laws whose supposed fixedness often interferes with freedom of thought.

Just where to draw the line that distinguishes a chemist from another worker, is a difficult, if not impossible task, for if we define a chemist, as one who is engaged in solving problems in the field covered by chemistry an industrial plant for instance, then we must include every individual connected with the plant, from the officers down to the common laborer for each in his own sphere, is engaged in working out some problem connected with the industry Consequently, a chemist, an industrial chemist in particular and all chemists are supposed to be industrial in some capacity is one whose occupation is that of solving problems arising primarily out of the chemical changes that are constantly taking place in the material universe, but which ultimately embrace every condition that contributes to the material happiness and comfort of mankind In fact his occupation is philosophical rather than scientific for instead of looking at things from a scientific point of view, that is from a fixed and limited principle, he learns to look at them from all points of view, which is the philosophical view

It has been said that to gain an education is to cultivate an attitude of mind that is to learn not merely to look at things but to learn how to look at them To merely look at things, is to look at them from one point of view which results in narrow mindedness prejudice and bigotry while the philosophical view cultivates a broad minded, altruistic attitude of mind and is productive of the greatest success and the greatest good to mankind

This is a point that might well be impressed upon chemical students lest they become deluded with the idea gathered from their study of the theory of chemistry that problems can be solved by the application of fixed principles and unchanged laws unconscious of the fact that their solution is in the end accomplished by adjusting and harmonizing conditions that are antagonistic and incompatible with any fixed principle that may be laid down in a text book Instructors in the natural sciences are too prone to impress upon their scholars the absoluteness of the laws of nature without taking the necessary precaution of drawing a distinction between theory and practice between science as organized common sense, and science as practical common sense The most successful chemist is the one who combines a well balanced amount of both the scientific and the practical mind for the problems that will confront him quire for their solution the broadest possible attitude of mind Even those who have had many years of experience are sometimes liable to be two scientific and to rely too much upon scientific deductions, as for instance when we have worked out some method to approximate perfection on a small scale and then make an attempt to apply it on a larger scale only to meet with failure and financial loss because some unforseen factor has arisen that intereferes with the operation

Summary of the Fifth Annual Report of the Carnegie Foundation

The fifth annual report of the president of the Carnegie Foundation covers the year ending September 30th 1910 The report is divided into two parts Part I pertains to the current business of the year Part II is a discussion of the Relation of the College and the Secondary School

The report shows that the trustees had in hand at the end of the year funds amounting to \$11 114,056 86 consisting of the original gift of \$10 000 000 par value of five per cent bonds and one million accumulated surplus The income for the year was \$543 881 90 During the year 64 retiring allowances were granted of which 46 were in accepted institutions and 18 in institutions not on the accepted list During the year 23 pensioners died

Among distinguished teachers who retired during the year were Professor Burt G Wilder of Cornell; Dean Van Amringe and Professor Chandler of Columbia both well advanced in years and in academic honors; Professor George L Goodale the famous botanist of Harvard Professor Osborne of the Massachusetts Institute of Technology who has taught mathematics in that institution since its foundation; Chancellor MacCracken of New York University President Seelye of Smith College and Professor Calvin M Woodward of Washington University St Louis These distinguished men average in age seventy two years and illustrate how well the vigor and influence of the scholar can be continued to a ripe maturity

There were admitted to the accepted list during the year the University of California the joint institutions of the State of Indiana Indiana University and Purdue University—and Wesleyan University the last named a college

In the first part of the report the president of the Foundation follows up the bulletin on Medical Education by a paper on the Relation of the University to the Medical School in which he calls attention to the responsibility attaching to any college or university which undertakes medical education

The second part of the report is a careful attempt to state the existing causes of friction between the secondary school and the college and the loss of educational efficiency in the present methods of bringing pupils from the school to the college The complaint of the college against the secondary school and the complaint of the secondary school against the college are set forth

An extremely interesting part of the report is a statement of the observations of Oxford tutors upon the preparation of the Rhodes Scholars The strong points in the American boy's preparation are readily seen by these trained teachers, and the weaknesses which they find point directly to the superficiality and diffusion of the work done in the American secondary school and college

The president of the Foundation urges that this whole question be approached by secondary school men and college men in a spirit of co-operation Neither the certificate method of admission nor the piecemeal examination method have in his opinion solved the problem He urges that the college must find a solution which will test better than the certificate or the piecemeal examination the fundamental qualities of the student, and which will at the same time leave to the high school a larger measure of freedom He recommends a combination of certificate and examinations, the latter of a simple and elementary character but calling for a high quality of performance without which the candidate will not be admitted For example under this plan the boy who cannot write good idiomatic English would not be admitted to college at all, but would be sent back to the secondary school The entrance requirements recently adopted at Harvard are quite in line with these recommendations The president of the Foundation urges a co-operation between the secondary school and the college not as unrelated institutions but as two parts of a common system of education He argues that the interest of the great mass of high school students must not be sacrificed to the interest of the minority who are looking toward college He insists on a larger measure of freedom for the secondary school but on the other hand he argues that the interest of the boy who goes to college and the boy who goes from the high school into business are alike conserved by learning a few things well, not by learning many things superficially The boy who has obtained such intellectual discipline is a fit candidate for college, whether he has studied one set of subjects or another without this intellectual discipline he is unfit alike for college or business It is therefore, in the opinion of the president of the Foundation, the plain duty of the college, at the present stage of American educational development, to articulate squarely with the four year high school and to leave the secondary school the largest freedom so that it may educate boys, not coach them; but at the same time to require of the candidates for admission tests which rest upon high performance in the elementary studies and which mean mastery of the fundamentals In such a program lies the hope of scholarly betterment and of civic efficiency for both college and high school

On the 28th of April the railroads of Russia will pass under the control of the Imperial Russian Technical Society This day also marks the opening of an international exposition in St. Petersburg devoted particularly to the application of electricity to railroad service

The Gold Dredging Industry

Old and New Fields for the Dredger

By Charles Janin

It is the contention of most engineers and operators familiar with the conditions, and is undoubtedly true to a great extent that the limits of dredging areas in California have already been fairly well defined, and that the greater portion of the field is controlled by the large interests. Other engineers are more optimistic and believe that tracts which have previously been passed over, or reported on unfavorably, when prospected some years ago still hold possibilities for the future. With the great advance made in the industry and the development of the modern dredge, from the earlier successful boats with their 600 cubic yards per day capacity to the boats with 16-foot buckets and the estimated capacity of 300 000 cubic yards per month, and the reduction of working costs, under favorable conditions, to less than 3 cents per cubic yard, it is obvious that areas which a few years ago were considered too low grade to equip with a dredge will under present conditions, again attract the attention of those interested in the dredging industry.

In Alaska there is a growing demand for dredges of the smaller class, having 2½ to 7 cubic foot buckets, a number of which have been installed in the last year and several of which are planned for 1911. In addition to these smaller boats, the Far North can boast of one of the largest dredges yet constructed, a Marion 16 foot bucket dredge installed on the Boyle concession in the season of 1910. This boat has a total weight of 900 tons and will dig approximately 10 000 cubic yards per day. On this same property a Marion 7 foot bucket boat has been successfully working since 1906 and is still in good condition for the past season it is said to have averaged 3,700 cubic yards per day.

Besides the possibility for new dredging areas in California and other western states and in Alaska the attention of dredge operators has been attracted to the many opportunities for the installation of dredges in foreign countries. Much interest has been manifested in Siberia of late and a number of American engineers have been engaged during the past year in the examination of Siberian gravel properties. A number if not all of these examinations resulted unfavorably some on account of the low grade of the gravel others because of severe business conditions or exorbitant prices imposed by the owners. However there is no question that so far as operating conditions are concerned there are areas of gravel in Siberia that can be profitably worked. Recent reports from the dredges operating in Siberia show an increased working efficiency both in the yardage handled and the percentage of gold recovered per dredge.

Recent engagements of experienced engineers for West Africa indicate that it is being more seriously considered as an attractive field for dredging investments. Some of the first dredges there as in other fields were failures but the employment of competent men is the first step toward obtaining reliable knowledge of existing economic conditions, and securing the installation of suitable dredges when they are warranted. This practice if more often followed would save investors much money and give a far better tone to the mining business in general.

It may be said that the majority of dredges placed in South America have been unprofitable. This has been due in part to a failure to recognize or to properly appreciate the difficulties of installing and operating a dredge under the conditions existing in South American countries and in part to equipping a property with unsuitable dredges on ground the value of which was optimistically guessed at rather than determined by careful sampling.

The most important dredging work in South America is that on the property controlled by the Oroville Dredging Ltd on the Nichi River in Colombia. The area was carefully examined by capable engineers and is probably the first South American property to be drilled and prospected in the systematic manner in which such work is done in California. Over 300 acres were proved to be profitable dredging ground. The company has a concession of 22 000 acres, the greater portion of which has not yet been prospected. A hydro-electric plant has been built and an 8½ cubic foot bucket dredge (California type) with steel hull will be built.

In French Guiana dredging has been tried so far on three rivers only the Carcibo, the Sparwin and the Lisard. Three new dredges are in course of construction in those places an indication that the first results, either in dredging or in prospecting have been encouraging. There are in French Guiana other rivers equally rich. According to the latest reports, a new dredge operating in Roche Creek carefully prospected in 1908 has given an output of 8 kilogrammes in March and 10 kilogrammes in April, 1910 (1 kilogramme of this gold is worth about $500). Experiments extending over a period of six months were made with an English dredge of 1 000 cubic meters estimated capacity a day but which owing to difficulties of operation was unable to wash more than from 300 to 400 cubic m in 24 hours. These experiments are said to have demonstrated that the cost of operation in handling this amount of gravel was from 36 to 42 cents per cubic yard.

An entertaining account of the Goldfields of French Guiana," by Albert Bordeaux from which the above paragraph was abstracted appears in the Trans Amer Inst Min Eng for November 1910.

In British Guiana dredges are successfully operated where the gravel is much lower in gold content than that of French Guiana. It might be that better results could be obtained in French Guiana by employing convict labor but thus far experiments in this direction have been far from encouraging, another attempt is to be made on a placer near S Jean du Maroni.

In Dutch Guiana gold dredging has been carried on along the Saramacca and Marowijne rivers with small Holland built dredges.

In Mexico several gravel areas have at times attracted attention. A dredge was installed at Suaqui Grande Sonora, some years ago but was not a success. Other places in Sonora along the Yaqui River near Tonichi and San Antonio were prospected with Keystone drills with indifferent results. A prospecting party is now drilling at the latter place but reports from it are not encouraging. The dry placers of Altar have been brought into prominence recently by the success of the Quenner dry washing machine. In Sinaloa there are places where it is claimed that the ground could be profitably dredged. The present outlook for gold dredging in Mexico however is not brilliant.

Among other fields that may be mentioned as offering possibilities for gold dredging are Korea China and the Philippine Islands. In Korea tests have been made of gravel areas and it has recently been reported that a dredge is to be erected. In China there has been no dredging but engineers consider that there are areas in the northeastern part which are worthy of investigation. The only successful dredging in the Philippine Islands has been carried on in the Paracale district which is situated in the northern part of the province of Ambos Camarines on the eastern coast of the island of Luzon. It has been described in "The Mineral Resources of the Philippine Islands" published by the Division of Mines of the Bureau of Science. The placer ground in the vicinity of Paracale generally consists of about four or five meters of barren clay mixed with organic matter overlying a varying amount of gray clay carrying small quantities of gold. Below this is an irregular layer of sand and quartz pebbles in places showing large amounts of free gold. Dredging operations have been carried on by the Paracale Gold Dredging Co, a New Zealand corporation the Stanley Paracale Co whose dredge is at present shut down and the Philippine Gold Dredging Co which bought a dredge originally erected on the island of Masbate. This last dredge was found unsuited to the ground on the Paracale River and was again moved this time to the Malaguit where it is said to be successfully worked.

The Paracale River is really an arm of the sea with a tide rise and fall of some 5 or 6 feet. The flat in which it runs is perhaps a mile wide near the mouth. It continues about the same width for a mile or more and then spreads out into smaller flats with ranges of hills between. The total area available for dredging in this flat is estimated at 1,300 acres. The average depth is 30 to 40 feet on the lower river; but higher where the Stanley dredge is working the depth is considerably less. The Malaguit River which flows into the Pacific not far from the Paracale has been prospected with hand drills. There is a much larger percentage of gravel and heavy material there than on the Paracale. Several other streams in the same district have been prospected to some extent, with results not altogether favorable. Low hills and ridges divide the tidewater streams, and except where cleared by the natives for growing hemp, are covered with heavy timber and a dense undergrowth, so that prospecting is difficult.

In Burma there are numerous gravel areas, some of which have been worked for generations by the Burmese who employed a rude method of ground sluicing. A number of these areas have been more or less thoroughly prospected and several dredges have been built, a number of which were failures. According to J Malcolm Maclaren in Gold Its Geological Occurrence and Geographical Distribution:

Of all Burma's numerous auriferous alluvial deposits none has been considered worthy of extended trial except those owned by the Burma Gold Dredging Co above Myitkyina. There three dredges were at work in 1907 with results considered so satisfactory that a fourth dredge of greater capacity was being built.

Figures for the past year are not at present obtainable but according to an article in The Mining Journal in November 1909 these three dredges worked six days a week for an average of 46 weeks and turned over a total of 1 918 000 cubic yards for the year with a total recovery of £32 000 ($155 520) or 8 cents per cubic yard. The operating cost including management is given at 3¼ cents per cubic yard. It is possible that dredges will be placed on other properties a California type Bucyrus boat has in fact been ordered by the Mewaing Gold Co Ltd.

In Japan according to a report recently issued by the Bureau of Mines:

From early times many placer workings have been carried on in the river beds or terraces along the river sides in the districts of Kesen Wakuya Hayakawa Abekawa, Yoshinogawa etc. Recently they have begun to be worked in many localities in the Hokkaido, and the River Kilung in Formosa. Up to the present time only the surface placers have received attention for which reason no gold dredging or underground working has been attempted. The largest nugget ever found in Japan weighed only 27.1 ounces and was found in the gold bearing gravel at Yesashi. The greater part of these deposits are in the Alluvium while a few of them are discovered in the Diluvium yet we never find any Tertiary placers.

In tropical countries there are many drawbacks that should be thoroughly understood by anyone purposing to invest in mining properties. Often rough mule trails are the only means of entering a district and the transportation of heavy machinery would be impossible until some kind of a road was built. Attempts to sectionalize dredges have not been as successful as with other classes of mining machinery. In Guiana the only means for transportation of machinery along the rivers is by canoe. One dredge failed to reach its destination because the hull pieces were too large to be taken over the first rapids. They are still to be seen along the trail. The attempt was made to remedy this loss by building a wooden hull on the ground but in that climate insects and worms destroy wood in a short time. The next hull ordered was made in smaller pieces.

Climatic conditions in the tropics are generally trying; the heavy rainstorms during the long wet seasons and malaria and beri beri are to be contended with. The inefficiency of native labor is also a serious matter though in some cases it has been possible to instruct natives to operate a dredge with a white overseer in control. There is always difficulty in securing and maintaining an efficient and honest staff of white labor so far from home and it is generally necessary to have a reserve corps to fall back on when occasion requires.

One engineer who has some interesting figures from an extensive examination in Colombia, mentions that his white assistants were incapacitated 16 2/3 per cent of the time from sickness. On another trip the young engineer in charge contracted a fever which proved fatal. In foreign countries as elsewhere in making investments in dredging much money may be saved and disappointment avoided if prospective investors will insist upon having reports by experienced engineers rather than listening to the advice of optimistic incompetents, and going blindly into enterprises that, to be an economic success, require experience and good judgment in every phase of the work.

* Condensed from an article in the Mining and Scientific Press of Dec 31st 1910.

The Block Signal on the New Paris Subway

The block signal system used on the new Paris north-south subway introduces an improvement over the former practice. When a train is stopped in the tunnel, all the other trains on the line are stopped and also in the tunnel. It is desired to prevent this and to allow the other trains to reach the next station before stopping. A special green light known as "permissive signal," allows of doing this. At the entrance of the block there are three signal lights, white, green and red and at the end, white and a double red light. When the train leaves the station, it automatically throws on the double red outgoing signal, so that if a train comes in the rear it finds the entrance signal at green (permissive) which shows that it can enter the station, but that there is a train in front of it within the tunnel. The rear train enters the station but is stopped there by the double red outgoing light. When the fore train reaches another station it annuls one of the red lights. The back train is still stopped by this red light, but it knows that the fore train has now reached a station. When the front train leaves its station it puts on the white light for clear track as usual. The green light is here used exceptionally as a "permissive signal" so as to allow the rear train to come into the station, but it can go no farther as it is stopped by the double red light or the single red. Thus the principle is kept of separating two trains by two red lights, but the two are now condensed on the same outgoing signal. By this method all the trains can enter the stations in front of them, even if one should be blocked in the tunnel, and the passengers can be discharged. On the old system when one train was stopped in the tunnel, all the others are likewise stopped and could not enter the stations.

Electric Works for the Production of Cast and Forged Steel

An electric steel works has been installed on a large scale at Dommeldange Luxemburg. It produces cast and forged steel and is now running at full production. Three blast furnaces give 330 tons of iron per day. For the steel process, Wellmann Talbot heating furnaces and Kjellin electric furnaces are used. Two of the latter are now in operation for use on single-phase current, and a third furnace is adapted for three phase current. The plant makes extensive use of blast furnace gas for running gas engines and also as boiler fuel. Steam turbines are run from the boilers. Especially noteworthy are the large Augsburg gas engines which are of special design for use in operating on the blast furnace-gas. This is first passed through scrubbers before going to the engines.

The Famous Astronomical Clock of Venice

The Church of St Mark and the Torre dell Orologio

By Charles A Bressler

The attention of the entire civilized world was recently attracted to Venice the white swan of cities, by the news that the Campanile one of the architectural attractions of the renowned plaza of St Mark which collapsed and was a heap of ruins in 1902 has been successfully rebuilt The disaster was attributed to the insecurity of the foundations in the swampy bottom and it was feared that other historical structures fronting on the show place were threatened with a similar fate The fact that this would be regarded as a catastrophe of world wide significance induced the Italian government to investigate the conditions of these historical structures, which include the Doge s palace the Church of St Mark and the *Torre dell Orologio* (clock tower) so called from its being the location of the famous Astronomical Clock of Venice

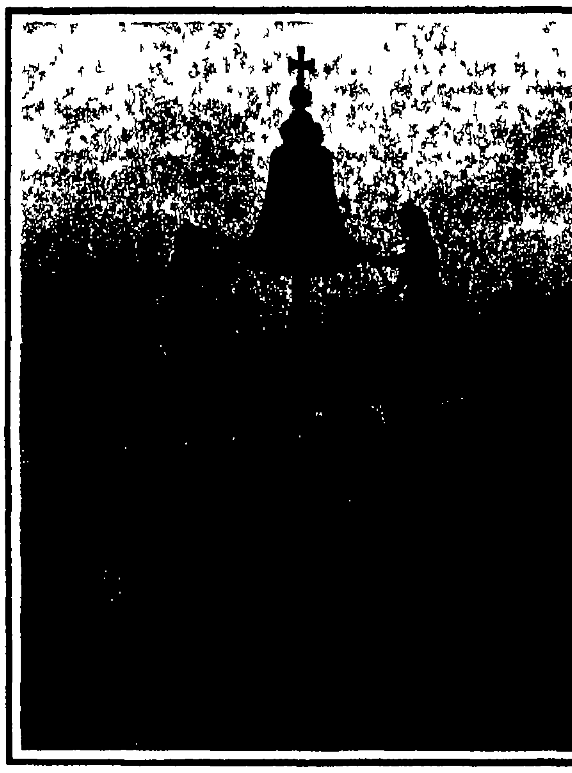
This last named building which is seventy feet in height and is of solid white marble with decorations consisting of panels of colored Carrara marble and mosaics of gold and lapis lazuli was erected for business purposes as early as the fifteenth century the archway in the center giving access to the *Merceria* the commercial center of Venice where the principal stores are to be found and the best retail trade is carried on Pietro Lombardo was

Projecting from the front of the tower above the clock is a balcony, in the center of which sits the Virgin Mary enthroned, a gilded figure, on a background of blue and gilded lattice patterns holding the infant Jesus on her knee, the figures being flanked by two doors, overlaid with gilded work Four times a day the doors open and a procession makes its appearance from the door on the right, first an angel blowing on a golden trumpet, then in turn the three kings or wise men from the East—Melchoir Caspar and Balthasar Each in passing raises his hand and bows his head, in salutation of the mother of God, enters the door on the left and disappears, the doors closing after the last figure has entered The procession moves before the Virgin at three six, nine and twelve o'clock and our special photograph showing this portion was taker at the moment when they were passing in front of the throne On a console above the canopy under which the Virgin sits, is a massive figure in bronze of the winged lion of St Mark Surmounting the tower are two bronze figures of Moors—the "bronze giants of Venice"—who strike hours and quarters on two large bells, hung one within the other

It is related of these figures that on one occasion, something having gone wrong with the striking mechanisms,

per minute, but it was found that 6000 revolutions was sufficient. In this work it was not sought to use the inertia of the gyroscope directly for the steadying, but the gyroscopes were employed for automatic working of the rudders charged with balancing the aeroplane at each instant. To carry this out, the gyroscopes were placed in a case which could turn by trunnions about an axis perpendicular to the rotation axis of the gyroscope. If the trunnion axis is placed in the direction of moving of the aeroplane, for instance, and if the aeroplane tends to incline upwards or downwards, the gyroscope reacts against this inclination by the movement which it has around the trunnion axis. Such movement is transmitted to the rudder by suitable connection. A first set of tests was made with the gyroscope and the rudder mounted together on a swinging frame like a large balance arm and working from a fixed point. The governor took the wind from the blowing machine used in Colonel Renard s experiments on airship models. Under these conditions, when the balance of the system was disturbed either by shifting movable weights on the arm or by bearing against this arm, it was seen that the rudder worked by the gyroscope gave the equilibrium automatically A second series of tests was

THE CLOCK JUST AT THE MOMENT WHEN THE THREE WISE MEN OF THE EAST ARE PASSING BEFORE THE VIRGIN AND INFANT



THE GIANT BRONZE MOORS STRIKING HOURS AND QUARTERS OF THE GREAT VENICE CLOCK OF ST MARK S

THE FAMOUS ASTRONOMICAL CLOCK OF VENICE

the architect of the tower which was built in 1494 the wings on each side also built in the style of his school were not erected until the beginning of the sixteenth century

The first clock installed in the tower was made by Giovan Paolo Rinaldi of Reggio and Gian Carlo, his son but in 1750 it was badly damaged by lightning and Ferracina of Bassano reconstructed it in 1775 Evelyn in his memoirs under date 1645 evidently refers to the first clock when he describes it as next to that at Strasburg for its many movements some of which he mentions his description indicating that many of the features of the original clock have been embodied in the present timepiece

One of our illustrations shows the great dial of the clock and the automata with which it is surmounted The dial bears on its outer circle the hours from 1 to 12 in Arabic figures twice repeated making the twenty four hours used in the Italian system of dividing time but subdivided to make them comprehensible to those accustomed to other methods of division The inner circle shows the signs of the zodiac and revolves at such speed as to show the months in their relation to the period The hour is indicated by the single hand there being but one in accordance with the old system of clock construction The body of this hand is concealed behind the center of the clock only the point in the form of a blazing sun showing beyond the groove between the first and second circles in which it travels around to point the hours The center of the clock is of black enamel spangled with golden stars to represent the heavens Its center is occupied by a golden sun around which a globe, half black half gilt makes a complete revolution in twenty-nine and a half days, reproducing the phases of the moon.

an attendant went up to investigate Incautiously, he ventured too near the hammer of one of the giants as it came into action was struck on the head and hurled to death on the pavement of the plaza Our photograph shows the figures outlined against the sky in the act of striking the bells

At the Franco-British Exhibition, held a short time since in London, a model of the old clock with the tower, twelve feet in height and closely following its construction as to materials, etc was exhibited It was beautifully executed and reproduced exactly the movements of the celebrated clock

It is to be hoped that every precaution will be taken by the proper officials to ascertain whether there is really any risk of further damage to the buildings grouped about the square of St. Mark of the nature that resulted in the destruction of the Campanile The world can ill afford to lose such specimens of the mechanical skill and artistic taste of bygone generations as the clock tower we have just described and the remaining edifices that make the Plaza of St Mark in the city of the Doges an object of interest to artistic pilgrims and students of human progress from all over the world

Gyroscope Rudders for Steadying Aeroplane Flight

New experiments have been made in France by M Girardville in the use of the gyroscope upon aeroplanes for steadying them when in flight. The author carried on experimental work at the Chalais-Meudon military aeronautic establishment near Paris The gyroscopes used here were constructed by M Delaporte and the revolving mass weighs 8.8 kilograms (19¾ pounds) The speed of rotation can reach 10,000 to 12,000 revolutions

made by transporting the whole to the top of the Eiffel Tower and operating under violent and often irregular winds of 40 to 50 feet per second The results were identical with the foregoing It should be remarked that at the beginning of the present work, the tests were hindered by the fact that under the action of the gyroscope rudder, the balance arm swings about its pivot and these movements may be very strong Such effects were, however all eliminated by using a dash-pot composed of a flat plate working in a vessel of water After making the above tests with fixed apparatus, M Girardville proceeded to try actual flights, and placed gyroscope rudders on aeroplane models, first unmanned and then upon aeroplanes without motors, mounted by an aeronaut, such as were used for simple gliding in former aeroplane work Such tests showed him that even with small sizes, having but 19 square meters (199.2 square feet) surface, the air reactions on the surface were enough to replace the effect of a dash-pot, so that in air flight there was no oscillation noticed. He made a number of flights, unbalancing the aeroplane by shifting the weight and working in irregular winds, and found that the gyroscope rudder always worked in the desired direction and enough to bring back the equilibrium. At present he is engaged in making experiments with aeroplanes carrying motor at the Vincennes military establishment at Paris, and is having encouraging results. During the first tests the motor operated the gyroscopes by flexible shaft and friction rollers Since then he adopts another method and secures good results by using an extra helice of small diameter which is placed so as to turn, under the action of the wind from the main aeroplane helice. The small helice thus drives the gyroscope by suitable mechanical movement.

The Pygmy People of Africa

Prof Starr's Discoveries in the Jungle

By Ethel Claire Randall, Ph M

In his Preface to Schweinfurth's "The Heart of Africa," Winwood Reade surmises that the pygmies were the original natives of Africa and that they "may be considered as the scattered remains of an aboriginal population now becoming extinct; and their isolated and sporadic existence bears out the hypothesis"; a supposition corroborated by De Quatrefages, who thinks that formerly these little people "formed populations denser and more continuous, that they have been crowded back, separated, divided, by superior races," and again, "whenever one meets with them to-day one sees them retreating, and often dying out." Keane, in spite of his cut-and-dried table of descent, holds a like view regarding the communities of little people as "all being scattered fragments of a primeval dwarfish race, who are to be regarded as the true autochthones of equatorial Africa" Stanley dwells upon the same thought: "These little people have roamed far and wide From the Niger banks, with successive waves of large migrants, they have come to pitch their leafy huts in the unknown recesses of the forest." "Their kinsmen are known as Bushmen in Cape Colony, as Watwa in the basin of the I ulungu, as Akka in the Monbuttu as Balia by the Mabode, as Wambutti in the Ihuru, and as Batwa under the shadows of the Lunae Montes"

Of the tribes going to make up the sum of this common dwarf race in Africa, the bulk of material accumulates about the *Akka*, the *Obongo*, the *Batwa*, and the *Wambutti* and still another small people, the *Bushmen*, concerning whom much has been said and written by way of contradictory opinion as to their connection with the members of the accepted pygmy race The first of these the *Akka* we are told appear to occupy a continuous area and to number nine distinct tribes, each with its own chieftain In comparison with the other races among whom they live, Schweinfurth states that they differ from them in scarcely any particular beyond the matter of height and in the tone of the complexion which is redder or brighter in shade He measured six adult males and a boy not yet grown None exceeded materially a height of four feet ten inches His statements are verified by those of Marno, Giglioli Chaillé-Long and Vossion

Junker fell in with the *Wochua* whom he assures us the the same as described by Scweinfurth though they call themselves *Achua* or *Wochua* indifferently in distinction to the name *Akka* or *Tickitikki* given them by the Arabs and *Affi* by the surrounding natives They are feared by those in their vicinity and pick and choose which tribe they will live near avoiding some consistently and neighboring with others whose chiefs frequently engage their help in warfare Their custom is to horde together in small communities rarely exceeding one hundred individuals nevertheless they have made their presence so thoroughly felt in their outskirts that they oftentimes stick an arrow into a bunch of green bananas, whereupon the owner not daring to pluck it, leaves that particular cluster to be claimed by them when ripe.

Du Chaillu in 'Equatorial Africa and the Country of the Dwarfs," speaks of a tribe of hunters in the neighborhood of the Niembousi totally unlike the *Ashango* in whose territory they live These *Obongo* frequently move from one place to another always taking care however to stay within certain confines They plant nothing It is not unusual for them to steal from the *Ashango* then decamp immediately to some more remote part of the district Yet, in spite of this, the *Ashango* are kind to the little folk, even appearing to like to have them in the neighborhood inasmuch as they can get exchange of meat from them for the agricultural products and manufactured articles such as iron implements, cooking utensils water-jugs and the like The *Ashango* and the *Obongo* however do not intermarry Their disposal of the dead is curious The corpse is put into the interior of a hollow tree, found somewhere deep in the forest, and the opening is closed with leaves, branches and earth. Still more interesting is the account vouched for by the *Ashango* who say that at other times the pygmies turn the current of a running stream in order to make a hole in the river-bed where they may place the body, and having suitably covered it allow the water to regain its accustomed course. Their dialect presents a mixture of their own original language and of that of the various tribes with whom they have come in contatt.

"In Darkest Africa" Stanley makes the statement that there is no evidence of polygamy and every evidence that domestic ties are strong among these little people Each family has its own hut, a low structure of the shape of an oval figure, cut lengthwise, fashioned of the stalks and leaves of the phrynia Other huts—those peculiar to the *Wambutti*—are elevated and made in a cone shape running to a sharp point from which emerges a central support projecting above the grass-thatched roof The huts are usually arranged in a circle with the doors varying from two to three feet in height, facing inward toward a hut in the center occupied by the chief and his family These miniature villages are planted in the midst of the forest several miles distant from a tribe of agricultural aborigines, and it is not uncommon occurrence for a large clearing occupied by big blacks engaged in tillage of the land to be surrounded at intervals by as many as a dozen communities of pygmies, aggregating in all perhaps two thousand five hundred souls. The approaches to a village are indicated by a series of diamond cuttings in the roots of trees across the track leading to it and at a distance of approximately five hundred yards, while within a hundred yards of the camp, along every trail leading to and from it, is a sentry box large enough to accommodate two persons and with a door facing the track, placed there as a toll gate for caravans. The occupation of the pygmies is hunting and fishing, and scouting for their agricultural neighbors, who, from the nature of their pursuits, are a settled community They are keen woodmen Large game they stalk in bodies and bring down by baiting with hundreds of arrows till it falls Game smaller or less agile than elephants buffalo and antelope, are trapped in pits covered lightly with sticks, leaves, and earth, and surmounted by a shed like structure with the roof suspended from a vine in order that it may fall at the right moment Animals still smaller than chimpansee, baboons, etc., and birds, are captured in bow-traps fashioned in such a way as to strangle them. The weapons of the dwarfs are tiny bows, and arrows tipped with metal, sometimes steel and poisoned, as well as spears and probably axes, since Stanley noticed that the trees in the vicinity of the pygmy camps were scored with ax cuts The division of labor is practically that known to every people in the state of barbarism: the women do the cooking, collect the fuel and the provisions, as well as carry the household goods when the camp moves, which it does whenever game becomes scarce in one region; the men employ themselves in making traps for game, nets for fishing, in working iron and steel, in carving ivory, which they cut into fantastic designs for bracelets, anklets and necklaces, and in manufacturing the deadly poison with which they smear the tips of the iron arrow-heads and lay thickly on the splints such as are made from wood.

Stanley relates, further, that he met with two types of dwarfs, the individuals differing from one another in complexion shape of head and in facial characteristics "Whether the *Batwa* forms one nation and the *Wambutti* another" he says, 'we do not know but they differ as much from each other as a Turk would from a Scandinavian He captured one of the dwarfs said to live north of the *Wakuma* country and later four women and a boy, one of whom evidently belonged to the *Akka* for she had "small cunning monkey eyes close and deeply set The other four possessed large round eyes full and prominent, broad round foreheads and round faces small hands and feet with slight prognathism of the jaws figures well formed though diminutive and of a brick tint complexion The monkey-eyed woman had a remarkable pair of mischievous orbs protruding lips over hanging her chin a prominent abdomen narrow flat chest, sloping shoulders long arms, feet turned greatly inwards and very short lower legs as being fitly characteristic of the link long sought between the average modern humanity and its Darwinian progenitors, and certainly deserving of being classed as an extremely low degraded, almost a bestial type of human being One of the women was of perfect proportions and "appeared at first to be but an undersized woman; but when we placed some of our Zanzibar boys of fifteen and sixteen years old by her side, and finally placed a woman of the agricultural aborigines near her it was clear to everyone that these small creatures were a distinct race"

Others who have discussed the *Batwa* are Dr Wolf Mr Hinde Mr Verner and Dr Starr A number of the points made by Dr Wolf have already been mentioned But their method of drying meat upon stagings over the fire has not been spoken of, nor their disposal of such

PROF STARR AND ONE OF THE PYGMIES

cured meat to the large negroes upon set market days held on ground common to the two camps Dr Wolf notes the servile position occupied by the dwarfs among their big neighbors and remarks, finally, that the bodily forms of the *Batwa* were well developed and entirely made the impression of normal

Mr Sidney Langford Hinde emphasizes their skill as bowmen and the deadliness of the poisoned arrows in use by the dwarfs while Mr Samuel Phillips Verner adds still further to our knowledge of their manner of life *It was Mr Verner who at the instigation of the Louisiana Purchase Exposition brought a group of Batwa* from the Congo Free State to St Louis His account of this drawfish race is to be found in an article published in the *Atlantic Monthly* for August 1902 and in his book entitled Pioneering in the Congo According to his information given by him the *Batwa* are fishermen as well hunt men they spread their nets both those for hunting and those for fishing upon poles under grass sheds their bows are of a crimson-colored wood strung with rattan fiber while their arrows are of bamboo notched at one end pointed at the other and coated with the black sticky gum which appears when the roots of a Euphorbia are boiled and pressed their food ranges from hippopotamus to white ant including locust caterpillars the ant dried in the sun besides all varieties of vegetable produce

With regard to their habit of hunting monkeys he tells how the *Batwa* clear half an acre of forest across which they stretch a net ten by forty feet and drive the monkeys from their haunts into the clearing dispatch them easily as they become enmeshed in the snare Baboon skins are prized for dress, or in the lack of this a yard of palm-fiber cloth Some women, however and the children, go unclad. Tattooing is not practised among them and beads, brass and copper wire are unknown, but gay feathers and amulets of bone or the skins of small animals are used for decorative purposes. The older men wear a scant beard. Such details of height and personal appearance as are cited by Mr Verner practically agree with those listed for all pygmies A *Bantu* proverb aptly illustrates their mental make up, "Sharp as a pygmy"

A recent visitor to the pygmy lands is Dr Frederick Starr whose paper upon the same people has but recently appeared among Ethnographic Notes from the Congo Free State: An African Miscellany' Dr Starr after a summary of the remarks of Wolf Hinde Bateman Stanley and Verner proceeds to report of his own contact with these little people that in addition to the numerous tables of measurements, deals with the structure of the *Batwa* huts, their ways of kindling fire by friction on wood and their custom of adorning the person by deeply cut and well marked temple scarring (of the matting or plaiting patterns)' and by clipping the teeth to blunt points Although at the commencement of his article Dr Starr owns to having expected to find in the *Batwa* typical pygmies" and to "have been in a confused frame of mind regarding them from first contact with them up till now and that What shall we do with the *Batwa* has been a harrassing question" he concludes "We believe that the *Batwa* should actually be classed with the true pygmies of the Ituri forest"—a statement strengthened by his elaborate comparison of a pygmy, a *dwarf* and a *Baluba* boy: "They are larger than we should like, but in type, face expression, character and mode of life, they are the same. Constancy of hunting, absence of agriculture, parasitic relation to large neighbors, shyness and distrust, despised condition, use of the bow and poisoned arrows, adherence to making fire by friction, all point one way To-day scattered and occurring here and there over a large area, they everywhere appear to have been the original occupants of the country'

One ethnologist divides the African negritos into three *branches upon his family tree of the Homo-Ethiopicus:* The *Akka* the *Wochua* and the *Batwa*—this last branching off into the *Obongo* on the one side and farther along into the fork of the *Hottentots* and the *Bushmen*. But a classification of this nature, even in the light of a review brief as the foregoing, can be seen to argue a somewhat strict division and subdivision not warranted by the information at hand The names, the number of races, if more than one, much less the course of development or branching of one tribe from another, is by no means clear as Keane's table would give us to understand *Certainly in view of the scarcity of actual scientific knowl*edge upon the subject, the attempt to prove that "all the tribes of Africa whose proper characteristic is an abnormally low stature belong to one and the self-same race" (Schweinfurth) *is of more consequence* than a hard-and-fast tabulation of tribes within that generalization of race

Prof. Van der Waals of Leyden

A Nobel Prize Winner

The eminent Dutch physicist Professor Van der Waals of Leyden who has just received one of the Nobel prizes is justly celebrated throughout Europe for his *contributions to the advancement of science* His name however is as yet little known in this country and this is the more strange because his fame largely rests upon his development and application of a scientific theory first promulgated by an American physicist W Gibbs

A writer in a recent number of *La Nature* gives an interesting *résumé* of Van der Waals achievements and their basis

Born at Leyden in 1835 he became celebrated upon the discovery of an equation which permits better than the *formula of Rankin and Hirn the expression of the char*acteristic relation of fluids i e the relation between specific volume pressure and temperature He has shown what expression should be substituted for each gas, in the laws of Mariotte and Gay Lussac when we endeavor to approximate reality To arrive at this he conceived the fecund idea of extending to gases the consideration upon which Laplace founded his theory of capillarity

The method adopted by the Dutch savant for governing the calculation and combining the results of diverse *investigation indicates a remarkable profundity of* thought; it is peculiarly attractive to those who study from the philosopher's point of view the genesis of the great theories of modern physics

Thanks to him the parallelism which has been observed in liquids with respect to certain special properties in definite conditions of temperature has taken on a general *character for all fluids whether liquid or gaseous* and a definite significance

Thus as Poincaré observes the Leyden physicist has given to the words corresponding states" a precise significance he has demonstrated that the specific constants of each body disappear in the characteristic equation when we take for units the values corresponding to critical points and that in corresponding states any two fluids have *precisely* the *same* properties

It may be remarked as was proved first by Natanson and afterwards by Prof Curie that the theory of corresponding states does not necessarily imply the exactitude of the formula of Van der Waals

But the last has not contented himself with studying the statics of a simple fluid He has regarded mixed fluids as *compositions of a vast number of particles* and has established an equation characteristic of mixtures which no longer depends on thermodynamic ideas as one might suppose but on mechanical hypotheses This equation has been made *the subject of a critical study by* Berthelot In short Van der Waals has extended his investigation to abnormal substances, associated or dissociated

One of his greatest services—a service both to science and to industry—was his appreciation and exploitation of the value of a remarkable treatise published in 1876 by *an* American physicist W Gibbs *on* The Equilibrium of Heterogeneous Substances"

This had remained practically ignored for fifteen years, until Van der Waals called the attention of the scientific world to it This *memoir* contained in practically complete form the theory of thermodynamic statics and the manifold applications of thermodynamics including notably the liquefaction of gases, are based on a profound study of this work

If certain biologic researches even lead to conclusions of the highest interest from the point of view of cosmogenic *hypotheses upon the cold of space* how many analogies in the immediate domain of applied science would be lacking if we were still ignorant of the famous law of phases and of the idea of eutexia thereto attached by Guthrie It is the application of this which permits the control and verification of complex facts such as the equilibrium between one or several bodies and the solution which contains them and, more generally which allows us to obtain a precise guide in critical investigations of chemical mechanics

These questions, apparently so theoretical are moreover of the greatest practical interest

Just as cryoscopic and tonometric measurements furnish to experimenters the easy solution of delicate problems of hygiene, such as the control of milk or other alimentary substances just as *isotonia* plays a more and more important part in medicine and physiology as is shown in the study of serums in the same way the law of phases facilitates the study of equilibriums in liquid or solid solutions such as the complex equilibrium between the salts of sea water the study of steels and metallic alloys, and the study of petroleums, glasses, cements and hydraulic mortars

If the physicist finds scientific interest of capital importance in the relation which defines the equilibrium of homogeneous gaseous systems, the engineer finds no less interest in the ability to obtain a precise knowledge of the phenomena of the reduction of minerals in gas furnaces

Finally the labors of Van der Waals have largely contributed to the establishment *of the fact of the existence* of a continuous passage of matter from the liquid to the gaseous state a point as important for the philosopher as for the scientist.

By his penetrating intellect his exact *reasoning* and his bold forecasts justified by later experiment Van der Waals has won a pre-eminent place among men of science The bestowal of the Nobel prize upon him will now make known to the enlightened public the name of this theorist whose investigations of the laws of kinetics have been so fertile in applications of industrial importance.

Resistance of Metallic Filament Lamps to Shock

The employment of metallic filament lamps is rapidly increasing because their consumption of electrical energy is only about one third that of carbon filament lamps of the same candle power while their price has fallen from 80 or 90 cents apiece to 40 or 50 cents The principal defect of metallic filaments is their fragility When cold they are easily broken by shock and vibration The filament itself is in less danger of breakage when heated by the current but then the same agencies often weld together filaments which are too slack or too near each other Hence the cost of renewal is large and these lamps cannot be used in railway or trolley cars, or in portable mountings

For these reasons it is important to determine the degree of sensitiveness to shock possessed by various metal lic filament lamps This has been done by suspending the lamp by a flexible wire and subjecting it to the impact of a rubber coated leaden bullet which rolls down an inclined track The force of the impact can be varied by varying the weight of the bullet and the length and inclination of the track

Dr F Lugrand has invented another apparatus for subjecting the filament to a series of shocks the intensity of which can be regulated The lamp is fastened on a board *AB* which turns on a hinge at *A* (Fig 1) The free end *B* of the board is alternately raised by the rotation of the spiral cam *c* and brought down again by the weight of the lamp and board assisted by the tension of the spring *R*

After falling through the distance *h* determined by the profile of the cam the board is suddenly arrested by striking the small part of the cam. The intensity of the shock which is thus given to the lamp is determined by the tension of the spring which can be varied and can be measured with a steel yard *In order to ascertain the* number of shocks that the filament can withstand before breaking an apparatus for counting the number of revolutions is attached to the shaft of the cam, which is turned by an electric motor at the rate of one revolution per second The key *ab* (Fig 2) in the circuit of the motor is kept closed while the lamp is burning by the relay *R*

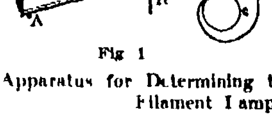

Fig 1

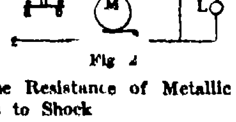

Fig 2

Apparatus for Determining the Resistance of Metallic Filament Lamps to Shock

which is traversed by the lamp current. When the filament breaks the key is opened by a spring, the motor stops and the number of shocks which the lamp has received is indicated by the registering apparatus In measuring the ability of the filament to resist shock when cold the lamp circuit is closed during only a small fraction of each second, by means of rotary commutator *C* keyed on the shaft of the cam The intermittent current thus produced does not greatly heat the filament, but it keeps the motor circuit closed by means of the relay until the filament breaks The number of shocks required to weld two heated filaments together can be determined by adjusting the relay so that it opens the motor circuit when the resistance of the lamp has been diminished by a certain amount of welding of the filaments.—*Le Génie Civil.*

Invar Wires for Geodesic Work

Wires of the new non-expansion alloy known as invar have been used for measuring in geodesic work in the Simplon Tunnel and in various scientific expeditions It is valuable for such uses as it keeps its length to a very close degree This metal it will be remembered is a nickel steel alloy with about 34 per cent nickel, and it expands but 1 10 the amount for iron hence it is coming into use for scientific work M C Guillaume, chief of the Weights and Measures Bureau of Paris, who prepared this alloy made tests with measuring wires in the basement of the establishment As a base he used lines drawn on nickel plates incrusted in heavy bronze soles, and these were cemented into the foundation walls, using six measuring marks at 19 feet apart, covering 79 feet of length He compared the measuring wires directly with this standard, stretching them by heavy weights and pulleys The wires carry measuring scales attached to their ends. Twelve wires gave almost identical lengths for some years, and any irregularities were found to be mainly due to the expansion of the wall itself. Several years observations allowed of establishing the variations of the wall, which were about two-thirds that of the wires. The wires do not vary at constan temperature, more than one-millionth, so that "invar" can be quite depended on. He also caused the wires to be expanded with heat up to about 40 degrees change and found that the expansion was very regular and there were no sudden changes A weight of about 90 pounds was used for stretching Before this, M Jäderin brought out a geodesic method using a steel and brass wire. The temperature was deduced from the difference of length, and we thence find the real length. By using invar we need but one wire and use but a rough estimate of the temperature.

Migrating Stars*

Old and New Star-Drift Theories

By J A Hardcastle, F R A S

The great doctrine of the Fixity of the Stars, has without question exerted a profound influence for good over the imagination of the human race, and the critic who casts it aside as merely an obsolete error only proves his own incapacity for criticism New conceptions of the stellar universe have arisen to replace it and will doubtless in their turn elevate the responsive mind, but the new must be built on the old or to use a truer metaphor the new must grow out of the old for intellectual change is no less organic than is our physical growth From the ancient doctrine of the incorruptibility of the heavens has sprung our own implicit acceptance of the Continuity of Nature that is to say, the permanence of what we call the Laws of Nature We need not fear to cast our imagination far into the future and contemplate the possibility of our present views undergoing as radical a change as has been the fate of the Fixity of the Stars, though we may not at present be able to suspect from what direction the new knowledge will come

It requires therefore no defence if we start with the statement that all the stars are moving we need not rely simply on the *a priori* inconceivability of the contrary, we have the observed fact that the angular distance between any pair of stars is not now the same as it was in the days of Bradley Nor need we here emphasize the great difficulty of grasping the precise meaning of the words Proper Motion but it will be obvious that any vagueness as to the technical contents of that phrase will tend to obscure our judgment when we discuss the indications of a sympathetic distribution of proper motions

These indications were first brought to light by Proctor[1] nearly forty years ago and to him we owe the origin of the expression "star drifts He showed that large groups of stars were animated by a motion across the sky in the same direction and at the same rate and we must admit the cogency of his argument that this cannot be regarded as accidental It is in fact, the fulfillment of the conjecture thrown out a century earlier by William Herschel in "The Philosophical Transactions" of 1783 in a paper entitled On the Proper Motion of the Sun etc The very title of that paper is [a] tification of the word of warning we have just uttered as to the difficulty of keeping quite clear the meaning of the term Proper Motion Even in a modern syllabus we have the expression The Proper Motion of the Sun used to describe its apparent annual motion among the stars so it is little wonder if the term Proper Motion is a stumbling block to many a beginner We may perhaps state here once for all that the Proper Motion of a star is the minute change of the *apparent* position which it occupies *with reference to the other stars* it would require too much space were we to attempt to bring out the full meaning of the words placed in italics

Proctor's word "drift has recently been appropriated to a far larger process of which he had no means of knowing The story of Kapteyn's "Two-Drift Theory" does not enter into the scope of this article, and we need some word which we can use for the much more limited groups to which we now refer By a happy inspiration Prof Turner has given them the name of "Migrating Stars [2] the various flocks of which need not, of course be moving in the same direction but the individual members of each flock will be distinguished by the fact that their motions are parallel and equal Some of the members of a flock may have passed us some may be passing on the right some on the left, while some are still approaching us Thus we may have to look to all points of the heavens to pick out the components of any one flock

'Parallelism and equality of motion are Proctor's words, and we shall presently see how the investigation has carried us now to a point where both those features vanish, and yet the main idea not only remains true but is vastly enlarged This is only one more instance of the growth of ideas the very characteristics by which originally they were defined are discarded and yet the idea remains

The best known cases of equal parallel motion are perhaps the Pleiades and the Great Bear The arrows in Fig 1 give by their length and direction the most recent values of the proper motions of those stars. Proctor's discovery is seen at a glance.

Five out of seven are moving in a common progress; the other two obviously do not belong to them In Fig. 2 we have the arrangement as it will be in 100,000 years, as seen by an observer in the solar system It may justly be urged with regard to Fig 2 that we are multiplying observed quantities by at least 1,000, and consequently their errors too The thousandth part of the length of one of the arrows is a mere point, the uncertainty then *of the direction* of that fraction must surely be very great. The criticism is unquestionably reasonable, and we cannot give the space now to meet it, but we can only state that not only is Fig 2 accepted by men who are competent to judge of the evidence, but also the much wider inferences to which we shall presently refer are considered sound by leading authorities

Before continuing the story of these five stars we will describe another flock of migrants detected by Prof Lewis Boss in the constellation of Taurus[3] Prof Boss of Albany will be remembered in the annals of astronomy "for his long-continued work on the positions and proper motions of fundamental stars,' to quote the words in which the award of the Gold Medal of the Royal Astronomical Society was made to him in 1905 One of the by products of his exhaustive and accurate work which by the way, was undertaken in order to stake out the 49th parallel of latitude as the boundary between Canada and the United States, was the detection of

Figs 1 and 2 are drawn from modern values of the proper star motions Fig 1 shows the equal parallel movement of five out of seven stars in a common progress the divergent stars not belonging to the flock Fig 2 shows the arrangement as it will be seen by an observer in the solar system in 100 000 years

the fact that 39 stars in Taurus have proper motions directed toward one spot on the celestial sphere He gave the name "the convergent for this point and it will be readily admitted that it must be the vanishing point of a sheaf of parallel tracks In this case the component stars are scattered over a circular region of the sky so large that six out of the seven stars of the Great Bear could lie on it As a cluster therefore those 39 stars are extremely loose and in no way catch the eye the individuals being quite faint stars Let the imagination however be projected forward some sixty million years and the convergence of the tracks will *have brought them all on to a smaller space than is* now occupied by the Pleiades If then the cluster will thus condense by mere perspective and the lapse of time may we not argue backwards and suggest that the compact clusters which we now see might have appeared many million years ago as mere scattered stars apparently quite dissociated and may we go on to suspect that the actual distances between components of a star cluster may be comparable to the distance which separates us from the nearest of our stellar neighbors To have written such words a couple of years ago would have laid one open to the charge of indulging in unguided speculation; this single group of stars has very

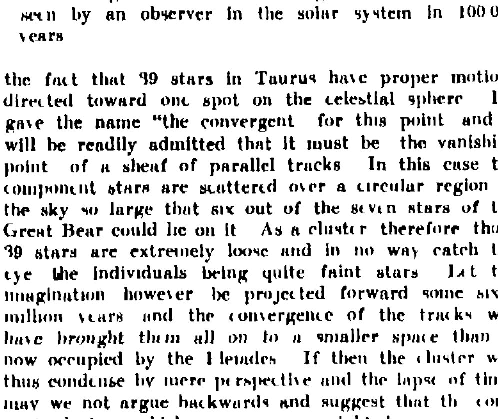

Fig 3 shows a diagram of a cube in perspective with the vanishing point Fig 4 diagram to aid in finding proper motion of star its velocity and distance

greatly widened the limits within which our imaginations may safely play

In this case, therefore the parallelism of Proctor's arrows has given place to a convergence of the apparent motions But the essential feature of parallel motion does not disappear; it is, in fact, brought out more strikingly, and a perspective is added which immensely increases the picturesqueness of the whole conception The impression that the starry sky is a mere shell or vault is only too easily forced upon us, but here we have a third dimension the depth of space illustrated vividly before our imagination

In Fig 3, which is the sketch of a cube in perspective with the vanishing point O of three edges shown we know that any other line parallel to those edges must, if produced go through O and for an inverse reason the line of sight from the observer's eye to O must be parallel to those edges

If then one looks at the vanishing point one is looking in a direction parallel to the lines that there vanish When shafts of light are seen radiating from the sun, we know that they are really all parallel and their common direction is given us by the line from our eye to the sun although it must be frankly admitted that it requires a real control over the imagination to make it assent to this unimpeachable truth Now the point O corresponds to "the convergent of Boss's cluster but supposing all his proper motions had been on the same lines but in the opposite direction then we should have to call O the divergent and the convergent will be in the diametrically opposite direction from O Suppose a rod pointing at O and suppose we look the other way along it our line of sight would be parallel still to the motions of the stars and we should be looking at "the convergent' We shall have to use this little *proposition in our next example of a flock of migrating stars*

Returning once more to Proctor's five stars his information only warranted him in asserting that the arrows were sensibly parallel the more precise determinations made by Dr Ludendorff from recent catalogues show us that those arrows are not parallel but the arrangement is only the more remarkable for they all diverge with extraordinary accuracy from a single spot at R A 123 deg Dec 37 deg N One might be tempted at first to exclaim that Proctor's whole foundation was obviously rotten if once parallelism is disproved it was pure luck that led him to associate these five stars and Fig 2 must also be unreliable And yet as a matter of fact we have drawn both in Fig 1 and Fig 2 from these modern values of the proper motions The divergent happens to be placed precisely on the line that so nearly passes through ζ ϵ δ and β at a distance to the right of β equal to twice the distance from δ to β We will call the divergent D and its antipodes which is therefore the convergent shall be C It is easy to picture these two points to oneself on the sky if one recalls the appearance of the Great Bear on a September evening lying in the northwest about as shown in Fig 1 D will then be the actual north point of the horizon and C will be the exact south point of the horizon (speaking for an observer in latitude 53 deg N) Accordingly at such a moment a rod placed horizontally north and south gives us *completely* the direction of the motion of this flock of stars past us Each arrow on the sky vault, giving a proper motion only indicates *partially* the direction of flight but if we may assume that the convergence means parallelism in perspective then we know from the convergent the *complete* motion relative to ourselves

Returning to the actual sky on the September evening at Sid time 20 hours i e about 8 P M on the 21st suppose we hold a square card with one edge horizontally north and south and tilt the west side up about 30 deg we shall find we can draw lines on it which will point quite straight to β δ ϵ and Ursæ Majoris (γ will be a little below the plane) and we will select β *for the moment to represent the group Let ON Fig* 4 be the edge of the card pointing horizontally north and Ou be directed to β The angle NOu will be 29 deg Then taking u anywhere on this line u can represent the star β and a line TC drawn parallel to NO represents the direction of β motion because it is pointing at C the "convergent or vanishing point For the present we know nothing about the magnitude of this motion in miles per second but let us take a length uc to represent this unknown velocity and we can split it up by the usual methods into ub perpendicular to uO and ua along uO

We must not say that ub is the proper motion of the star because proper motion is an angle and ub in our diagram is a distance but they are related by the fact that ub equals the angular motion multiplied by O the distance of the star

Now the distance of none of these stars is known and it is an interesting fact that from the detection of their convergent motion we can deduce their distance for we shall presently see that we can calculate the value of ub and we know of course the angular motion In the case of β this is 8 7 sec per century

Pass now to the components Ua which is the radial or line of sight motion of the star Dr Ludendorff has elaborately discussed this question which is extremely difficult for reasons which we must pass over For β he obtains the value 16 8 kilometers which means an approach of 10½ miles per second We may therefore say that ua 10½, and since the angle $Cua = NOu$ 29 deg we can deduce that $uc = 11½$ and we have at once the velocity of progress of the whole system it is 11½ miles per second Now we can go on to compute ub which must be 11½ cos 61 deg = 5½ and a little arithmetic will show that if β moves 8 7 seconds per century and this is really 5½ miles per second β must be about 400 billion miles away this would mean a parallax of about 0 05 second which is by no means unreasonable It may be of interest to remark that according to Prof Kapteyn's statistical estimates a star of the magnitude of β with a proper motion comparable to that of β might be expected to have a parallax of 0 025 second This may be regarded as quite a fair agreement

So far we have spoken only of β; it will be well to

[3] Astr Journal, No. 604.

have it clear what quantities we demand from the other stars if they are accepted as parts of the same flock

(1) Their proper motions must diverge from D—or converge on C

(2) Any known facts about their distance, radial motion, and amount of proper motion must fit in with the assumption that the velocity of the flock is 11½ miles per second. It is extremely unfortunate that for these stars the radial velocities are difficult to ascertain because they appear to be variable. Dr Ludendorff establishes β as a spectroscopic Binary and satisfies himself that ε is so too while ζ has long been so recognized. He obtains for ε and ζ the radial velocities — 13 and 12.6 kilometers (8.08 and 7.83 miles). If they belong to the flock those quantities should be 18.9 and — 18.9 (8.20 and 7.58) so this is a fairly strong corroboration but the main strength of the argument in favor of these five forming a flock is the convergence of their directions of proper motion, and their general similarity of magnitude and spectrum and possible duplicity.

We now come to a very pleasing development of this research. Dr Hertzsprung has sought for other possible members of this flock not confining his scrutiny to the immediate neighborhood of Ursa Major. The two criteria above mentioned were his guides the former of the two being naturally first applied. He found six stars whose motion fairly well converged on the point C R A 303 deg Dec -37 deg and one would naturally expect that some such result would emerge in reviewing any extensive list of stars. We must not then give much weight to the possible connection unless the second criterion is also satisfied.

Now the only star among the six for which we have the necessary information as to radial velocity and distance is Sirius, and the fact that the evidence is entirely satisfactory will be an exceptionally popular addition to stellar astronomy.

In the first place, the arrow of Sirius's proper motion is directed nearly precisely to the point C, and since the length of that arrow is ten times as great as any of Proctor's five stars it affords to that extent a more delicate test. Then the parallax of Sirius is well determined, the Nautical Almanac only recognises officially three parallaxes—those of Sirius and Centauri, and 61 Cygni, giving that of Sirius the value of 0.37 second. The radial velocity of Sirius has known many vicissitudes, and is at present accepted as —7.4 kilometers that is to say the Sirian system is approaching us at 4.6 miles per second.

On the September evenings, when C and D are so conveniently placed on our horizon, Sirius is not far from the Nadir; but without troubling to give the steps of computation it will suffice to state that the second criterion would demand from Sirius the following qualifications:

Parallax should be	0.387";	it is 0.37"
Radial velocity should be	—8.5;	it is —7.4

This second justifies us in stating with confidence that Sirius belongs to the same flock as Proctor's five stars, and Mr Eddington has remarked: "It would have been an interesting theme for the classical mythologists to explain how so important a part of the Great Bear has come to be situated between the teeth of the Great Dog."

There are two further striking inferences to be made from the distances which this discussion discloses. The actual stars of the Great Bear must be from 30 to 130 times as luminous as our sun—which places them, according to Kapteyn's estimates, among the larger of the heavenly bodies, for he only admits about 12 per cent. of the stars to be intrinsically more luminous than the sun. And, secondly, this stream, the existence of which is now accepted, comprises within its limits stars separated from each other by distances up to 30 light-years, say 600 billions of miles.

We pointed out at the beginning of this article that the doctrine of the Fixity of the Stars, immeasurable though its value has been, must now be abandoned, but we may begin to see that its place will be filled by another conception no less stimulating. In the place of the incorruptible crystalline sphere with its fixed stars we have opening gradually before us the appalling picture of the immensity of the universe. The utilitarian who points to navigation and to frontier-staking as the uses of astronomy merely convicts himself of being a shallow philosopher.

Making Money Out of Bees—III*

Keeping Bees for Pleasure and Profit

By E F Phillips, Ph D, in charge of Bee Culture, Bureau of Entomology

Concluded from Supplement No 1834, page 126

PREPARATION FOR THE HARVEST

An essential in honey production is to have the hive overflowing with bees at the beginning of the honey flow so that the field force will be large enough to gather more honey than the bees need for their own use. To accomplish this the bee keeper must see to it that brood rearing is heavy some time before the harvest and he must know accurately when the honey flows come so that he may time his manipulations properly. Brood rearing during the honey flow usually produces bees which consume stores while brood reared before the flow furnishes the surplus gatherers. The best methods of procedure may be illustrated by giving as an example the conditions in the white-clover region.

In the spring the bees gather pollen and nectar from various early flowers and often a considerable quantity from fruit bloom and dandelions. During this time brood rearing is stimulated by the new honey but afterwards there is usually a period of drought when brood rearing is normally diminished or not still more increased as it should be. This condition continues until the white clover flow comes on usually with a rush when brood rearing is again augmented. If such a condition exists the bee keeper should keep brood rearing at a maximum by stimulative feeding during the drought. When white clover comes in bloom he may even find it desirable to

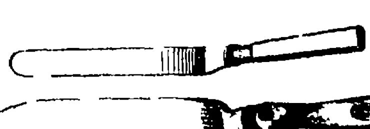

Fig 18 Knives for Uncapping Honey

prevent brood rearing to turn the attention of his bees to gathering.

A worker bee emerges from its cell twenty-one days after the egg is laid and it usually begins field work in from fourteen to seventeen days later. It is evident therefore, that an egg must be laid five weeks before the honey flow to produce a gatherer. Since the flow continues for some time and since bees often go to the field earlier than fourteen days, egg laying should be pushed up to within two or three weeks of the opening of the honey flow. In addition to stimulative feeding, the care of the colony described under the heading of Spring management will increase brood production.

THE PRODUCTION OF HONEY

The obtaining of honey from bees is generally the primary object of their culture. Bees gather nectar to make into honey for their own use as food but generally store more than they need, and this surplus the bee keeper takes away. By managing colonies early in the spring as previously described, the surplus may be considerably increased. The secret of maximum crops is to "Keep all colonies strong."

Honey is gathered in the form of nectar secreted by various flowers, transformed by the bees, and stored in the comb. Bees also often gather a sweet liquid called "honeydew," produced by various scale insects and plant lice, but the honeydew honey made from it is quite unlike floral honey and should not be sold for honey. It is usually unpalatable and should never be used as winter food for bees. When nectar or honeydew has been thickened by evaporation and otherwise changed the honey is sealed in the cells with cappings of beeswax.

It is not profitable to cultivate any plant solely for the nectar which it will produce but various plants, such as clovers alfalfa and buckwheat are excellent honey plants

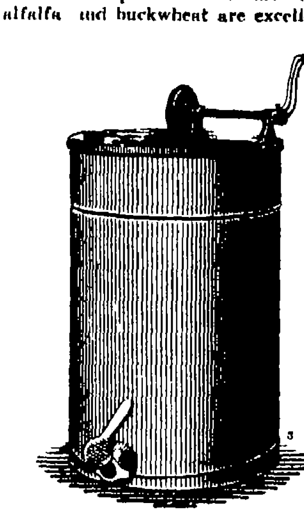

Fig 19—Honey Extractor

as well as valuable for other purposes. Their cultivation is therefore a benefit to the bee keeper. It is often profitable to sow some plant on waste land; sweet clovers are often used in this way. The majority of honey-producing plants are wild and the bee keeper must largely accept the locality as he finds it and manage his apiary

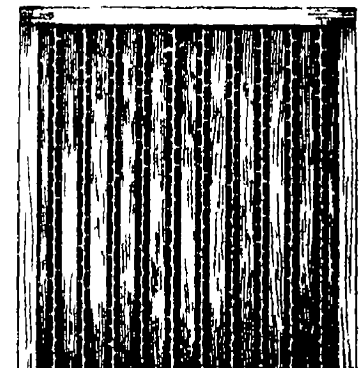

Fig 20—Perforated Zinc Queen Excluder

so as to get the largest possible amount of the available nectar. Since bees often fly as far as two or three miles to obtain nectar, it is obvious that the bee keeper can rarely influence the nectar supply appreciably.

EXTRACTED HONEY

Extracted honey is honey which has been removed by means of centrifugal force from the combs in which the bees stored it. In providing combs for the storage of honey to be extracted the usual practice is to add to the top of the brood chamber one or more hive bodies just like the one in which brood is reared and fill these with frames. If preferred, shallower frames with bodies of proper size may be used, but most honey extractors are made for full size frames. The surplus bodies should be put on in plenty of time to prevent the crowding of the brood chamber and also to act as a preventive of swarming.

Honey for extracting should not be removed until it is well ripened and a large percentage of it capped. It is best, however, to remove the crop from each honey flow before another heavy producing plant comes into bloom, so that the different grades of honey may be kept separate.

The frames containing honey to be extracted are removed from the hive, the cappings cut off with a sharp, warm knife (Fig 18) made specially for this purpose, and the frames are then put into the baskets of the honey extractor (Fig 19). By revolving these rapidly the honey is thrown out of one side. The basket is then reversed

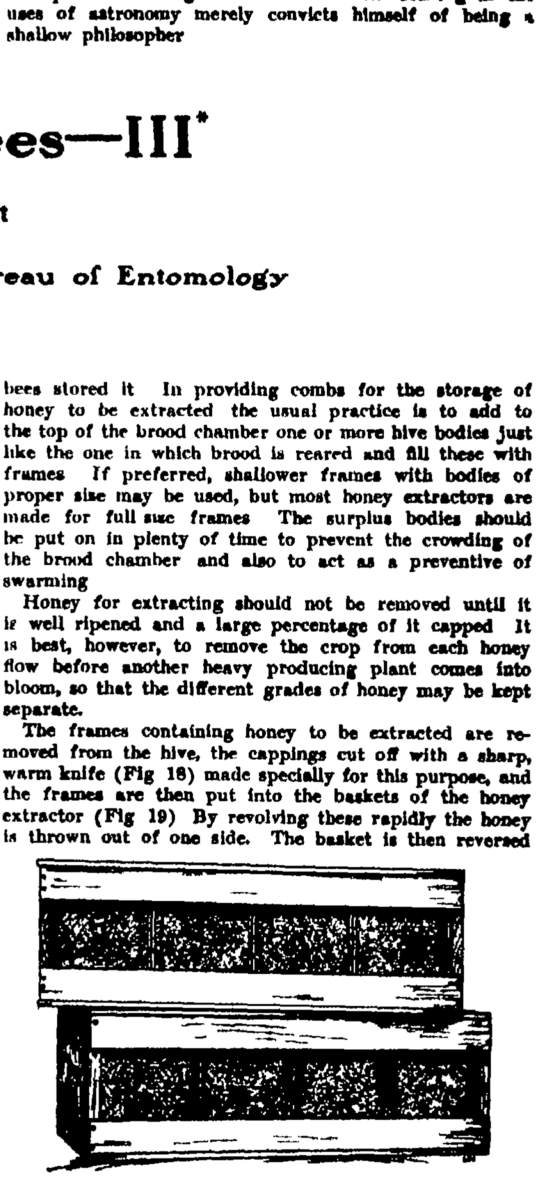

Fig 21—Shipping Cases for Comb Honey

and the honey from the other side is removed. The combs can then be returned to the bees to be refilled, or if the honey flow is over, they can be returned to the bees to be cleaned and then removed and stored until needed again. This method is much to be preferred to mashing the comb and straining out the honey, as was formerly done.

The extracted honey is then strained and run into vessels. It is advisable not to put it in bottles at once, but to let it settle in open vessels for a time, so that it can be skimmed. Most honeys will granulate and become quite hard if exposed to changes of temperature, and to liquefy granulated extracted honey it should be heated in a water bath. Never heat honey directly over a stove or flame, as the flavor is thereby injured. The honey should never be heated higher than 160 deg F, unless it is necessary to sterilize it because of contamination of disease.

Extracted honey is put up in bottles or small tin cans for the retail trade, and in 5-gallon square tin cans or barrels for the wholesale market. Great care must be exercised if barrels are used, as honey will absorb moisture from the wood, if any is present, and cause leakage. The tin package is much to be preferred in most cases. In bottling honey for retail trade, it will well repay the bee keeper or bottler to go to considerable expense and trouble to make an attractive package, as the increased price obtained will more than make it up. Honey should be heated to 160 deg. F., and kept there for a time before

*Farmers Bulletin No 397 U S Department of Agriculture.

bottling, and the bottle should be packed as full as possible and sealed hermetically.*

COMB HONEY

Comb honey is honey as stored in the comb by the bees, the size and shape being determined by the small wooden sections provided by the bee keeper. Instead of having comb in large frames in which to store surplus honey, the bees are compelled to build comb in the sections and to store honey there (Fig 2). A full section weighs about 1 pound; larger ones are rarely used. By the use of modern sections and foundation the comb honey now produced is a truly beautiful, very uniform product—so uniform in fact that it is often charged that it must be artificially manufactured. The purchaser of a section of comb honey may be absolutely certain, however, that he is obtaining a product of the bees, for never has anyone been able to imitate their work successfully. To show their confidence in the purity of comb honey, the National Bee Keepers Association offers $1 000 for a single pound of artificial comb filled with an artificially prepared sirup.

There are several different styles of sections now in use, the usual sizes being 4¼ inches square and 4 inches by 5 inches. There are also two methods of spacing so that there will be room for the passage of bees from the brood chamber into the sections and from one super of sections to another. This is done either by cutting "bee ways" in the sides of the sections and using plain flat separators or by using "no bee-way" or plain sections and using "fences"—separators with cleats fastened on each side, to provide the bee space. To describe all the different supers or bodies for holding sections would be impossible in a bulletin of this size, and the reader must be referred to catalogues of dealers in bee-keeping supplies. Instead of using regular comb-honey supers some bee keepers use wide frames to hold two tiers of sections. It is better, however to have the supers smaller so that the bees may be crowded more to produce full sections. To overcome this difficulty shallow wide frames holding one tier of sections may be used. The majority of bee keepers find it advisable to use special comb-honey supers.

In producing comb honey it is even more necessary to know the plants which produce surplus honey and just when they come in bloom than it is in extracted honey production. The colony should be so manipulated that the maximum field force is ready for the beginning of the flow. This requires care in spring management, and above all the prevention of swarming. Supers should be put on just before the heavy flow begins. A good indication of the need of supers is the whitening of the brood combs at the top. If the bees are in two-hive bodies they should generally be reduced to one, and the frames should be filled with brood and honey so that as the new crop comes in the bees will carry it immediately to the sections. If large hives are used for the brood chamber it is often advisable to remove some of the frames and use a division board to crowd the bees above. To prevent the queen from going into the sections to lay, a sheet of perforated zinc (Fig 20) may be put between the brood chamber and the super (Fig 2).

It is often difficult to get bees to begin work in the small sections, but this should be brought about as soon as possible to prevent loss of honey. If there are at hand some sections which have been partly drawn the previous year these may be put in the super with the new sections as bait. Another good plan is to put a shallow extracting frame on either side of the sections. If a few colonies in the apiary that are strong enough to go above still refuse, lift supers from some colonies that have started to work above and give them to the slow colonies. The super should generally be shaded somewhat to keep it from getting too hot. Artificial swarming will quickly force bees into the supers.

To produce the finest quality of comb honey full sheets of foundation should be used in the sections. Some bee keepers use nearly a full sheet hung from the top of the section and a narrow bottom starter. The use of foundation of worker-cell size is much preferred.

When one super becomes half full or more and there are indications that there will be honey enough to fill others the first one should be raised and an empty one put on the hive under it. This tiering up can be continued as long as necessary but it is advisable to remove filled sections as soon as possible after they are nicely capped, for they soon become discolored and less attractive. Honey removed immediately after capping finds a better market, but if left on the hive even until the end of the summer the quality of the honey is improved. A careful watch must be kept on the honey flow so as to give the bees only enough sections to store the crop. If this is not done a lot of unfinished sections will be left at the end of the flow. Honeys from different sources should never be mixed in the sections, as it gives the comb a bad appearance.

To remove bees from sections, the super may be put over a bee escape so that the bees can pass down but can not return, or the supers may be removed and covered with a wire-cloth-cone bee escape.

After sections are removed the wood should be scraped free of propolis (bee glue) and then packed in shipping cases (Fig 21) for the market. Shipping cases to hold 12, 24 or 48 sections, in which the various styles of sections fit exactly, are manufactured by dealers in supplies. In shipping these cases, several of them should be put in a box or crate packed in straw and paper and handles provided to reduce the chances of breakage. When loaded in a freight car the combs should be parallel with the length of the car.

In preparing comb honey for market it should be carefully graded so that the sections in each shipping case are as uniform as possible. Nothing will more likely cause wholesale purchasers to cut the price than to find the first row of sections in a case fancy and those behind of inferior grade. Grading rules have been adopted by various bee keepers' associations or drawn up by honey dealers. The following set of rules are in general use:

Eastern Grading Rules for Comb Honey

Fancy. All sections well filled, combs straight, firmly attached to all four sides, the combs unsoiled by travel stain or otherwise; all the cells sealed except an occasional one; the outside surface of the wood well scraped of propolis.

A No 1. All sections well filled except the row of cells next to the wood; combs straight; one eighth part of comb surface soiled, or the entire surface slightly soiled; the outside surface of the wood well scraped of propolis.

No 1. All sections well filled except the row of cells next to the wood; combs comparatively even; one eighth part of comb surface soiled, or the entire surface slightly soiled.

No 2.—Three fourths of the total surface must be filled and sealed.

No 3.—Must weigh at least half as much as a full weight section.

In addition to this the honey is to be classified according to color, using the terms white, amber and dark; that is, there will be Fancy White, No 1 Dark, etc.

New Comb Honey Grading Rules Adopted by the Colorado State Bee Keepers Association

No 1 White. Sections to be well filled and evenly capped except the outside row next to the wood; honey white or slightly amber; comb and cappings white and not projecting beyond the wood; wood to be well cleaned; cases of separatored honey to average 21 pounds net per case of 24 sections; no section in this grade to weigh less than 13½ ounces. Cases of half separatored honey to average not less than 22 pounds net per case of 24 sections. Cases of unseparatored honey to average not less than 23 pounds net per case of 24 sections.

No 2 Light Amber.—Sections to be well filled and evenly capped, except the outside row next to the wood; honey white or light amber; comb and cappings from white to off color, but not dark; comb not projecting beyond the wood; wood to be well cleaned. Cases of

separatored honey to average 21 pounds net per case of 24 sections no section in this grade to weigh less than 13½ ounces Cases of half separatored honey to average not less than 22 pounds net per case of 24 sections Cases of unseparatored honey to average not less than 23 pounds net per case of 24 sections

No. 3 This includes all white honey and amber honey not included in the above grades sections to be fairly well filled and capped no more than 25 uncapped cells exclusive of outside row permitted in this grade wood to be well cleaned no section in this grade to weigh less than 12 ounces Cases of separatored honey to average not less than 19 pounds net Cases of half separatored honey to average not less than 20 pounds net per case of 24 sections Cases of unseparatored honey to average not less than 21 pounds net per case of 24 sections

THE PRODUCTION OF WAX

Beeswax which is secreted by the bees and used by them for building their combs is an important commercial product There are times in almost every apiary when there are combs to be melted up, and it pays to take care of even scraps of comb and the cappings taken off in extracting A common method of taking out the wax is to melt the combs in a solar wax extractor This is perhaps the most feasible method where little wax is produced but considerable wax still remains in old brood combs after such heating Various wax presses are on the market or one can be made at home If much wax is produced the bee keeper should make a careful study of the methods of wax extraction as there is usually much wax wasted even after pressing

PREPARATIONS FOR WINTERING

After the main honey flow is over the management must depend on what may be expected later in the season from minor honey flows If no crop is to be expected the colony may well be kept only moderately strong so that there will not be so many consumers in the hive

In localities where winters are severe and breeding is suspended for several months great care should be taken that brood rearing is rather active during the late summer so that the colony may go into winter with plenty of young bees In case any queens show lack of vitality they should be replaced early so that the bees will not become queenless during the winter

The important considerations in wintering are plenty of young bees a good queen plenty of stores of good quality sound hives and proper protection from cold and dampness

If as cold weather approaches the bees do not have stores enough they must be fed Every colony should have from 25 to 50 pounds depending on the length of winter and the methods of wintering It is better to have too much honey than not enough for what is left is good next season If feeding is practiced honey may be used but sirup made of granulated sugar is just as good and is perfectly safe If honey is purchased for feeding great care should be taken that it comes from a healthy apiary otherwise the apiary may be ruined by disease *Never feed honey bought on the open market* The bees should be provided with stores early enough so that it will not be necessary to feed or to open the colonies after cold weather comes on Honeydew honey should not be left in the hives as it produces dysentery" Some honeys are also not ideal for winter stores. Those which show a high percentage of gums (most tree honeys) are not so desirable but will usually cause no trouble

In wintering out of doors the amount of protection depends on the severity of the winter In the South no packing is necessary and even in very cold climates good colonies with plenty of stores can often pass the winter with little protection but packing and protection make it necessary for the bees to generate less heat and consequently they consume less stores and their vitality is not reduced Dampness is probably harder for bees to withstand than cold and when it is considered that bees give off considerable moisture precautions should be taken that as it condenses it does not get on the cluster An opening at the top would allow the moisture to pass out but it would also waste heat so it is better to put a mat of burlap or other absorbent material on top of the frames The hive may also be packed in chaff leaves, or other similar dry material to keep out the cold Some hives are made with double walls the space being filled with chaff these are good for outdoor wintering The hive entrance should be lower than any other part of the hive so that any condensed moisture may run out The hives should be sound and the covers tight and waterproof

Entrances should be contracted in cold weather not only to keep out cold wind but to prevent mice from entering There should always be enough room, however for bees to pass in and out if warmer weather permits a flight

In the hands of experienced bee keepers cellar wintering is very successful but this method requires careful study The cellar must be dry and so protected that the temperature never varies more than from 40 to 45 deg F 43 deg F seems to be the optimum temperature The ventilation must be good or the bees become fretful Light should not be admitted to the cellar and consequently some means of indirect ventilation is necessary

Cellar wintering requires the consumption of less honey to maintain the proper temperature in the cluster and is therefore economical Bees so wintered do not have an opportunity for a cleansing flight often for several months but the low consumption makes this less necessary Some bee keepers advocate carrying the colonies out a few times on warm days, but it is not fully established whether this is entirely beneficial and is usually not practiced

The time for putting colonies in the cellar is a point of dispute, and practice in this regard varies considerably They should certainly be put in before the weather becomes severe and as soon as they have ceased brood rearing The time chosen may be at night when they are all in the hive, or on some chilly day

The hives may be piled one on top of the other, the lower tier raised a little from the floor The entrances should not be contracted unless the colony is comparatively weak It is usually not considered good policy to close the entrances with wire cloth, as the dead bees which accumulate more or less on the bottom board may cut off ventilation, and the entrance should be free so that these may be cleaned out

The time of removing bees from the cellar is less easily determined than that of putting them in. The colonies may be removed early and wraped in *black* tar paper or left until the weather is settled. If the weather is very warm and the bees become fretful, the cellar must either be cooled or the bees removed. Some bee keepers prefer to remove bees at night, so that they can recover from the excitement and fly from the hive normally in the morning One of the chief difficulties is to prevent the bees from getting into the wrong hives after their first flights They often "drift" badly with the wind, and sometimes an outside row will become abnormally strong, leaving other colonies weak

DISEASES AND ENEMIES.

There are two infectious diseases of the brood of bees which cause great losses to the bee-keeping industry of the United States These are known as American foul brood and European foul brood Both of these diseases destroy colonies by killing the brood, so that there are not enough young bees emerging to take the place of the old adult bees as these die from natural causes The adult bees are not attacked by either disease. In the hands of careful bee keepers both diseases may be controlled and this requires careful study and constant watching In view of the fact that these diseases are now widely distributed throughout the United States, every bee keeper should read the available literature on the subject, so that if disease enters his apiary he may be able to recognize it before it gets a start The symptoms and the treatment recommended by this Department are given in another publication which will be sent free on request.

It is difficult for a bee keeper to keep his apiary free from disease if others about him have diseased colonies which are not properly treated The only way to keep disease under control is for the bee keepers in the neighborhood to cooperate in doing everything possible to stamp out disease as soon as it appears in a single colony The progressive bee keeper who learns of disease in his neighborhood should see to it that the other bee keepers around him are supplied with literature describing symptoms and treatment, and should also try to induce them to unite in eradicating the malady Since it is so often impossible to get all the bee keepers in a community to treat infected colonies properly and promptly, it is desirable that the States pass laws providing for the inspection of apiaries and granting to the inspector the power to compel negligent bee keepers to treat diseased colonies so that the property of others may not be endangered and destroyed This has been done in a number of States, but there are still some where the need is great and in which no such provision has been made When no inspection is provided bee keepers should unite in asking for such protection so that the danger to the industry may be lessened

In case there is an inspector for the State or county he should be notified as soon as disease is suspected in the neighborhood Some bee keepers hesitate to report disease through fear that the inspector will destroy their bees or because they feel that it is a disgrace to have disease in the apiary There is no disgrace in having colonies become diseased, the discredit is in not treating them promptly The inspectors are usually if not universally good practical bee keepers who from a wide experience are able to tell what should be done in individual cases to give the best results with the least cost in material and labor They do not destroy colonies needlessly and, in fact, they all advocate and teach treatment

The brood diseases are frequently introduced into a locality by the shipping in of diseased colonies or more often the bees get honey from infected colonies, which is fed to them, or which they rob from discarded honey cans It is decidedly dangerous to purchase honey on the market, with no knowledge of its source, to be used in feeding bees. Many outbreaks of disease can be traced to this practice. It is difficult to prevent bees from getting contaminated honey accidentally If colonies are purchased, great care should be taken that there is no disease present Whenever possible, colonies should be purchased near at home, unless disease is already present in the neighborhood

There are other diseased conditions of the brood known to bee keepers as pickled brood but these can usually be distinguished from the two diseases previously mentioned The so-called "pickled brood" is not contagious and no treatment is necessary Bees also suffer from "dysentery," which is discussed in the earlier part of this bulletin and from the so-called "paralysis," a disease of adult bees. No treatment for the latter disease can as yet be recommended as reliable The sprinkling of powdered sulphur on the top bars of frames or at the entrance is sometimes claimed to be effective, but under what circumstances it is beneficial is unknown.

A number of insects, birds, and mammals must be classed as enemies of bees, but of these the two wax moths, and ants, are the only ones of importance. There are two species of moth, the larger wax moth (*Galleria mellonella* L.) and the lesser wax moth (*Achroia grisella* Fab), the larvæ of which destroy combs by burrowing through them* Reports are frequently received in the Department that the larvæ of these moths (usually the larger species) are destroying colonies of bees. It may be stated positively that moths do not destroy strong healthy colonies in good hives, and if it is supposed that they are causing damage the bee keeper should carefully study his colonies to see what other trouble has weakened them enough for the moths to enter Queenlessness, lack of stores, or some such trouble may be the condition favorable to the entrance of the pest, but a careful examination should be made of the brood to see whether there is any evidence of disease. This is the most frequent cause of the cases of moth depredation reported to this Department. Black bees are less capable of driving moth larvæ out, but, even with these bees, strong colonies rarely allow them to remain. The observance of the golden rule of bee keeping "Keep all colonies strong," will solve the moth question unless disease appears

Moth larvæ often destroy combs stored outside the hive. To prevent this the combs may be fumigated with sulphur fumes or bisulphid of carbon in tiers of hives or in tight rooms. If bisulphid of carbon is used, great care should be taken not to bring it near a flame, as it is highly inflammable. Combs should be stored in a dry, well ventilated, light room

In the warmer parts of the country ants are often a serious pest. They may enter the hive for protection against changes of temperature, or to prey on the honey stores or the brood The usual method of keeping them out is to put the hive on a stand the legs of which rest in vessels containing water or creosote Another method is to wrap a tape soaked in corrosive sublimate around the bottom board

GENERAL INFORMATION

For the purpose of answering numerous questions which are asked of this Department the following brief topics are included.

BREEDERS OF QUEENS

There are a large number of bee keepers who make a business of rearing queens of good stock for sale. The queens are usually sent by mail. If poor stock is all that can be obtained locally, it is recommended that such colonies be purchased and the queens removed and replaced with those obtained from a good breeder This Department can supply names of breeders nearest the applicant, of any race raised in this country

INTRODUCING QUEENS

When queens are shipped by mail they usually come in cages which can be used for introducing If the colony to receive the new queen has one, she must be removed and the cage inserted between the frames The small hole leading into the candy compartment is uncovered and the bees gradually eat through and release the queen If queens are reared at home a similar cage may be used for introducing

In view of the fact that disease may be transmitted in mailing cages it is always a wise precaution to remove the new queen and destroy the accompanying workers and the cage and its contents The queen may then be put into a clean cage without worker bees with candy known to be free from contamination (made from honey from healthy hives) and introduced in the regular way Queens sold by breeders are always mated unless otherwise specified and consequently the colony in which they are introduced has no effect on the offspring During the active season the bees in the colony are all the offspring of the new queen in about nine weeks Three weeks is required for the previous brood to emerge (if the colony has not been queenless) and in six weeks after all the old brood emerges most of the workers from it will have died

DEALERS IN BEE KEEPERS SUPPLIES.

There are several manufacturers of supplies in this country who can furnish almost anything desired by the bee keeper Some of them have agents in various parts of the country from whom supplies may be purchased thus saving considerable in freight.

BEE KEEPERS' ASSOCIATIONS.

There are a large number of associations of bee keepers in all parts of the country, formed for the betterment of the industry and a few associations which are organized to aid the members in purchasing supplies and in selling the crops. Of these the National Beekeepers Association is the largest. It helps its members in obtaining their legal rights, and aids in securing legislation for the furtherance of the industry The annual conventions are held in different parts of the country, and copies of the proceedings are sent to the members. There are also numerous state, county and town associations, some of which publish proceedings The names of officers of the nearest associations or of the National Beekeepers' Association will be sent on request from this Department.

LAW AFFECTING BEE KEEPING

Disease inspection.—Various States have passed laws providing for the state or county inspection of apiaries for bee-disease control, and every bee keeper should get in touch with an inspector when disease is suspected, if one is provided. The inspectors are practical bee keepers who fully understand how to control the diseases, and are of great help in giving directions in this matter The name of the inspector of any locality can usually be furnished, and this department is glad to aid bee keepers in reaching the proper officers.

Laws against spraying fruit trees while in bloom.—The spraying of fruit trees while in bloom is not now advised by economic entomologists, and to prevent the practice

*Circular 79, Bureau of Entomology, U. S. Department of Agriculture. The Brood Diseases of Bees.

*Bee keepers refer to these insects as moths, wax moths," "bee moths," "millers," "wax worms," "honey moths," "moth worms," "moth millers" and "grubs." The last two names are not correct.

some cities have passed laws making it a misdemeanor. Such spraying not only kills off honeybees, causing a loss to the bee keeper, but interferes with the proper pollination of the blossoms and is thus a detriment to the fruit grower. Bee keepers should do everything in their power to prevent the practice.

Laws against the adulteration of honey.—The National Food and Drugs Act of 1906, and various state pure food laws, are a great aid to the bee keeper in preventing the sale of adulterated extracted honey as pure honey. Bee keepers can often aid in this work by reporting to the proper officials infringements of these laws which come to their notice.

When bees are a nuisance.—Some cities have passed ordinances prohibiting the keeping of bees in certain areas, but so far none have been able to enforce them. If bees are a nuisance in individual cases, the owner may be compelled to remove them. The National Beekeepers' Association will help any of its members in such cases, if they are in the right, as well as in cases where bees sting horses. Bee keepers should be careful not to locate bees where they can cause any trouble of this kind.

SUPPOSED INJURY OF CROPS BY BEES.

Bee keepers are often compelled to combat the idea that bees cause damage to fruit or other crops by sucking the nectar from the flower. This is not only untrue, but in many cases the bees are a great benefit in pollinating the flowers, making a good crop possible. A more frequent complaint is that bees puncture fruit and suck the juices. Bees never puncture sound fruit, but if the skin is broken by some other means bees will often suck the fruit dry. In doing it, however, they are sucking fruit which is already damaged. These and similar charges against the honeybee are prompted by a lack of information concerning their activities. Bees may of course become a nuisance to others through their stinging propensities, but bee keepers should not be criticised for things which bees do not do.

Some Mental Illusions of Vision

Explanations of Various Optical Phenomena

By R. T. Lewis, F.R.M.S.

NOTWITHSTANDING the popular saying that "seeing is believing," neither of our faculties is subject to such complete illusions as our sense of sight, some being optical, others ocular, while again others are purely mental.

To the first kind belong those due to refraction—such for instance as the mirage or the apparent displacement of an object from its true position; to the second kind may be referred the phenomena of irradiation and of subjective images and colors; while the third includes the impression which most persons have of the apparent increase of the size of the Sun and Moon when rising or setting and the similar increase in the apparent size of constellations or the distance apart of stars when seen near the horizon as compared with our estimate of such at their meridian altitude.

That this last named illusion is neither optical nor ocular is shown at once by the fact that when seen through a telescope no such apparent increase is found to exist; indeed, when accurately measured after making all necessary corrections for height of barometer, temperature, and refraction in altitude, it is found that the apparent diameter of either body is really greatest when on the meridian, inasmuch as they are then some 4,000 miles nearer to us than when near the horizon, though the difference is too small to be appreciated by the naked eye.

It should be noted, however, that the amount of the apparent augmentation varies considerably with individuals; artists for instance depict the rising moon of a variety of exaggerated sizes up to about 15 deg. diameter, or about thirty times greater than it should be drawn, and one not infrequently hears it described as looking as large as a dinner plate, whereas a three penny bit held at arm's length is rather larger than is necessary to hide it completely.

That this almost universal illusion is entirely mental is not easy to demonstrate, although it will be readily admitted that if a false impression of the distance of an object can be created the mental estimate of its actual size will be proportionately altered. In other words, if an object we believe to be near to us appears of a certain size, and one of the same kind believed to be at a distance appears also of the same size, we at once from experience correctly judge that the latter must be the larger of the two. Hence though the Moon, whether high or low in the sky, practically subtends the same angle and therefore its image on the retina of the eye is in both positions the same, we naturally from experience imagine it must be a larger body in the latter case, because though so much farther off it appears to be of the same size as the Moon we see when apparently nearer.

The experiment referred to in the accompanying diagram affords a convincing illustration of the curious mental effect produced by the creation of a false impression of distance, and is one which may be performed by any persons who possess sufficient control of the eyes to dissociate the focusing and the convergence, which though quite separate and independent actions are from constant habit usually performed automatically together. *A B* represents a stereoscopic slide which we will suppose to be of the full Moon placed at the normal distance of ten inches from the eyes, when the two pictures are seen clearly in focus. If while retaining the focal distance we alter the convergence so that the axis of the right eye (*R*) passes centrally through the picture *B* and that of the left eye (*L*) through the center of *A*, as shown by the two firm lines *L C* and *R C*, these axes will meet at the point *C*, which will be more or less distant from the plane of *A B* according to the width apart of the eyes of the observer. The result of this will be that three images of the pictures *A* and *B* will be seen, of which the central one, consisting of *A* and *B* superposed, will be seen apparently at *C* and of course perfectly stereoscopic. If then without altering the distance between the eyes and the slide we look so cross eyed that the axis of *R* passes centrally through *A* and that of *L* through *B*, as indicated by the two dotted lines, we shall again see three images, the center one apparently at *D*, but in this case pseudoscopic. It is clear that in both cases the images of the pictures on the sympathetic portions of the retina will be approximately the same, but in the former case, where the Moon is seen apparently at *C*, or much farther off than it really is, the effect is that of a considerably magnified image, whereas in the latter case, where the picture is seen apparently at *D*, or much nearer than it really is, the mental impression produced (after making due allowance for the difference between *R A* and *R B*) is that of a considerably smaller Moon than either of those seen at *A B*, the mental illusion in each case being due to the fact that a false idea has been created as to the distances of the objects observed.

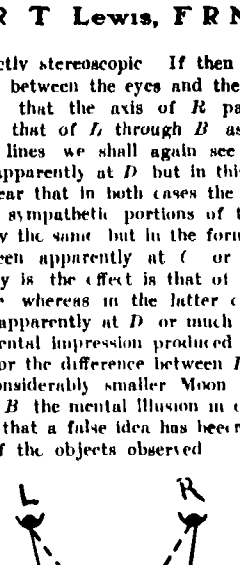

Diagram Illustrating False Impressions of Distance.

A further experiment may be suggested by means of the subjective image of any object which is gazed upon long enough to produce a continued impression upon the eyes. If for instance the filament of an incandescent electric lamp is steadily looked at for a few seconds, the impression produced by it upon the sympathetic portions of the eyes will persist until the vibrations so excited have run down, and a spectral image of the filament will meanwhile be seen so long as the convergence of the eyes is maintained at the same angle as when the lamp was originally looked at. If this image is projected upon the distant wall of the room it will appear of magnified proportions, whereas if thrown upon some surface nearer to the eye than the exciting cause it will apparently be seen of very reduced dimensions, although in both cases the actual picture formed must be precisely the same.

As yet another, though somewhat different class of mental illusion in the case of vision, I may mention that I have before me a photograph of the "Challenger" medal taken under a strong oblique light falling upon it from the top. Knowing from experience that if the light falls in that direction upon a raised surface the shadows would fall as depicted, the mental impression produced when the top of the photograph is held toward a source of light is that of a design in strong relief, although the sense of touch assures me it is flat; but if the picture is turned round so that the light falls upon it from the bottom experience immediately suggests that shadows, as they then appear, can only be thrown by an intaglio, and the mental suggestion is that of a sunk pattern, an illusion which would be complete but for the fact that the inscription still reads the right way about.

A false estimate of distance, and therefore of size, is very common to persons in the clear air of high mountainous regions who under ordinary circumstances are accustomed to see landscapes through our own more murky atmosphere, and the common illusion of meeting suddenly with gigantic figures in the street on a foggy night because they are much closer than imagined will occur to most people.

It seems also quite within the limits of possibility that some of the errors of interpretation as to the meaning of what is seen under the microscope may be due to mental suggestion.

It will be understood that the extent of such illusions as have been referred to varies somewhat according to the personal equation of the observer, and that what has been described is simply the experience of the writer, who it may be of some interest to mention has since he thought out the matter almost entirely lost the impression that the Sun and the Moon appear larger when rising or setting than at other times, though he has been quite unable to divest himself from the illusion in the case of constellations or stars.—*Knowledge.*

Moving Picture Camera as a Hand Camera by Using a Gyroscope

AT a recent meeting of the Société de Physique of Paris, an interesting method of taking moving picture views was presented by M. De Proszynski. Heretofore such a camera had to be mounted on a tripod to keep it quite steady and it was generally turned by a hand crank. The inventor succeeds in making a hand camera for use in taking such views. He keeps it steady by using the principle of the gyroscope in an ingenious way, so that holding it in the hand causes no trembling. But the problem was how to drive the gyroscope and also the film machine, as an electric motor with a battery is not practical, neither is a spring motor. He uses a small compressed air motor devised for the purpose, and it is very compact. It gives no shocks when running, which is, of course, an essential point. A unique feature is that an ordinary bicycle pump is used to fill the air cylinder of the motor, so that the whole can be made in the form of a hand camera about the size of a large kodak, and it is thus self contained. The inventor showed what the camera would do by projecting some street views on a screen. These were taken when moving the camera about in the hand quite rapidly, and the images were remarkably sharp. We expect to illustrate this apparatus in the near future.

TABLE OF CONTENTS

INDEX OF INVENTIONS

For which Letters Patent of the United States were Issued for the Week Ending February 21, 1911

AND EACH BEARING THAT DATE

[See note at end of list about copies of these patents.]

Bottle tube non breakable siphon O L. Koscborak 984,984
Box See Boiler fire box.
Box covering machine C B Baldwin 984 641
Bracket, W G Venard 985 079
Brake beam Bauer and Fowler 984 848
Brake for baby carriages and the like W D Woodler 983 737
Brazing apparatus L H Le Claire 984 708
Broom holding and displaying device H. G Druding 985 017
Brush J Kennedy 984 930
Bucket well, C B Fleet 984 638
Buckle shield E A. Flueger 985 057
Cabinet kitchen A W Macon 984 951

PILE DRIVER EMPLOYED IN CONSTRUCTING A MINING CONCRETE PIER IN SPAIN

A SPANISH MINING CONCRETE PIER.—[See page 159]

The Chemistry of Cellulose*

A Substance Little Understood

By Carl G. Schwalbe

The first attempts to substitute other prime materials for rags, old linen or cotton waste, for the manufacture of paper date from the middle of the eighteenth century. Even at this time these prime materials were getting scarce. Christian Schaeffer of Ratisbon attempted in 1765 to make paper from wasp nests, turf, straw, hay, the twigs of hops, from brush broom, and even from wood, but his efforts brought no results except the contempt and jeers of his contemporaries; the time had not yet come to realize this idea, and moreover the scarcity of rags had not yet become pressing. But when the development of daily newspapers and the necessity of satisfying the demand arising from the extension of popular instruction had made these ideas acceptable, the search of substitutes for rags became permissible; thus it was that towards the middle of the nineteenth century the attempts of the weaver Keller to de-fibre wood so as to obtain a pulp to replace the pulp from rags were favorably considered. There should be remembered too the attempts made by Melliers, among others, who frequently tried to treat straw so as to extract from it a pulp which could be used industrially. Cellulose treated with soda soon followed the mechanical wood pulp and straw pulp. In fact the process of treating wood, as well as straw, with caustic alkalies or alkaline earths became a success. Moreover, very soon after this alkali process had been brought from America to Europe by Houghton, it found a competitor in the chalk process or in the sulphurous acid or bisulphite process. The names of Tilghman and of Ekman are connected with the first experiments made in Germany to use calcium sulphite or magnesium sulphite for this treatment. At this time this process, which had been kept secret, fell into oblivion. The energy and determination of Mitscherlich and his licensees developed a practical industrial process which, concurrently with the analogous process of Rittner-Kellner, soon brought the new industry to an extraordinary stage of development in the short space of twenty-five to thirty years.

The production of cellulose amounted to 1 600 000 tons of the value of $80 000 000; the production in Germany was estimated at 564 000 tons worth $28 000 000; the proportion of cellulose treated with caustic soda was very small. This was due to the fact that for various reasons still disputed the bisulphite process of treating wood seemed superior to the soda process. However, in spite of the considerable extension of this process, in spite of the great progress it has made as to the yield both in quantity and quality of the product, hence the certainty of the methods of manufacture, still the cellulose industry depends almost entirely on empiricism. The chemical composition of the raw material wood and of its manufactured product cellulose is still almost completely unknown to us.

The cellulose industry and its allied industries of cotton, gun cotton, and artificial silk are thus in an analogous condition to some other industries, for example the leather industry; from this point of view they are in a totally different condition from the great industry of inorganic chemical products or of coloring matters. In the case of these last industries, the exact chemical knowledge of their raw materials and of their intermediary products has allowed them to advance very methodically and in well chosen paths, and this has made their recognized brilliant development possible.

May I be permitted here to make a rapid sketch of what the cellulose industry and its allied industries are; to point out what problems are not yet solved, the solution of which is demanded as much by the chemist as by the technical man, and to express how necessary it is to base these industries upon more solid chemical knowledge than they actually possess at present?

To begin with, let us consider the manufacture of mechanical wood pulp; 500 000 tons, worth $12 500 000, are produced annually in Germany. At first sight this manufacture does not seem chemical. In fact, the decorticated wood is crushed flat between millstones and under a stream of water either perpendicularly to the course of the fiber or with the fiber; the fibrous pulp thus obtained is refined, freed from splinters of wood, and then worked in different ways so as to yield various products, such as straw board, but chiefly the substance to which a small quantity of cellulose is added to make the paper for the daily journals.

If one of the stages which this process has lately reached is studied, that known as the method of refibring by the hot process which came from America, we are plunged at once in a chemical problem. In this method as a preliminary treatment, recourse is had simultaneously to boiling water and a very high pressure, working at as low a temperature as possible.

Boiling with water under these conditions, when it is for a short time only, appears to dissolve a certain part of the wood and to yield a very large quantity of very long fibers, with a small residue of broken fibers. The effect naturally goes much further if the water is allowed to act for too long a time and under greater pressure. To obtain very resistant fibers, certain constituents of the wood are dissociated and then the custom is to recover them by the production of the brown mechanical pulp. This pulp is specially used to make a very strong leather board. Unfortunately, carbonisation begins during this process. According as the temperature and the pressure (four atmospheres on the average) are more or less high, a correspondingly more or less marked brown color is produced. Is this due to the formation of humus? As vanillin and acetic, formic, and oxalic acids are found in the residual lye, it is not improbable that oxidation is set up.

It has been attempted to remove this extremely troublesome brown color by bleaching, but in vain. However there appears to be some hope of success of preventing the production of this brown color, that is of preventing the oxidizing agents from acting, to effect this, either the air in the autoclave (digester) and in the pores of the wood is removed by producing a vacuum in the autoclave, or, before boiling, the wood is impregnated with a solution of a reducing agent, such as sodium sulphide. Besides this question of discoloration, other technical problems present themselves; in any case there is the utilization of the residual lye which may contain as much as ten per cent of the weight of the treated wood. The solution of this problem opens up many scientific questions: From what portion of the ligneous substance are the organic acids derived? Is the process an hydrolysis? Above all, what is wood? And if in the course of our researches we take up those which refer not only to the mechanical pulp of brownwood, but also those which concern the white mechanical pulp, how is it that the paper made from mechanical wood pulp turns brown so quickly? And how shall we determine the amount of wood in a mechanical pulp when it is mixed with other fibrous substances? Very recently Messrs. Cross and Bevan have answered this question by an approximate solution. A solution of phloroglucin in hydrochloric acid gives a beautiful purple color to wood, which has long been used for the colorimetric determination of the quantity in mechanical wood pulp. But the two English savants have found that, as well as this color reaction, there is a notable absence of phloroglucin by the wood pulp in fixed proportions by weight. If wood pulp or a substance containing wood pulp is placed in a solution of phloroglucin of known strength, and at the end of a certain time the strength at that time of the solution is determined, the quantity of phloroglucin consumed allows a conclusion to be drawn as to the amount of wood in the pulp.

The absorption of an inconsiderable quantity (six to seven per cent) of phloroglucin by lignin, led Cross and Bevan to recognize in this fact a proof that only the ketone compounds and not the aldehyde compounds act in this way, for the aldehyde compounds will have been oxidized by the chlorine and could not give this reaction. This assumption formulated by the English scientists, on the presence of compounds reacting in the lignin, leads us to recognize quickly the hypotheses which have been made on the subject of lignin. Scientists are agreed in admitting that there must be an aromatic nucleus in lignin. Czapek by heating sawdust (wood shavings) in water under pressure obtained a substance which he called *hadromal* which was recognized later, thanks to the work of Graefe, as being a mixture of vanillin, methyl furfurol and pyrocatechin. Graefe concluded that from the quantity of methoxy compounds in the wood the quantity of vanillin could be deduced, and further that this must be the chief constituent of lignin. It is not necessary, however, that all of the methylic compounds should produce the vanillic nucleus, as Fromherz has shown. Moreover it appears very probable, according to the recent researches of Klason, that lignin is composed of coniferyl alcohol (a compound closely related to vanillin) and of a derivative of this alcohol, oxyconiferyl alcohol, for four similar nuclei have been formed by separating the water. This constitution would be allied to that of the carbohydrates and should be of the same character as a glucoside. In fact when water acts upon wood a solution is obtained containing ten to twelve per cent of a wood gum, which is a carbohydrate, from which proportion the content of lignin is deduced as twenty-six to thirty per cent. It is remarkable that invariably only 1.4 per cent of carbohydrate is found in the residual lyes of the bisulphite process; it must be admitted, then, that the pressure, the rise in temperature, and the chemical agents have a destructive action. Let us remark, in passing, that it is possible after that to answer the question so many times asked, whether it is not possible to manufacture vanillin by utilizing either the residual lyes derived from the hot process of making wood pulp or the lyes from the bisulphite process. At the very low price of $4.55 per pound, which is the present price of vanillin, no one would be interested sufficiently to make the extraction. Besides, it must first be considered that the demand for vanillin is not so important now, and that if this question was solved, it would not solve the problem of utilizing not only the cellulose, but also the lignin of wood.

These considerations have led us face to face with that problem of the cellulose industry which is the most difficult to solve and at the same time the most important. What will become in the future of those innumerable organic substances dissolved in water, when our rivers refuse to accept them; or what will remain, even of the business itself, when the laws protecting water courses, threatening even now, become active, and forbid us to throw the residual lyes into them in such large quantities as has been done up to the present time? The quantity of organic matter dissolved in water is nearly equal to the 564,000 tons of cellulose, and a means must be found of destroying it.

Having given the outline of this discussion, it is impossible to detail the numerous processes which have been suggested for the utilisation of the residual lyes. However, that attention may be called to the most recent of the processes in this direction, it will suffice to mention the one now on trial at Langen in Hesse. By heating the residual lye from the chemical wood pulp of the bisulphite process in the presence of acids and, when required, applying pressure and adding formaldehyde, a tough and plastic body precipitates. The question now is to ascertain if this product really has such desirable properties as will allow of its use in such a way as to assure a large demand for it. This product may be considered as cellulose pitch. This is the name given to the product obtained at Walsumam Niederrhein by evaporating the residual lyes nearly to dryness, and has proved to be an excellent agglutinant for the agglomeration of powdered minerals. The whole question lies in knowing if, in such a case, the cost of evaporation would not be too great, in which event the process is of no value from an economic point of view.

In the production of cellulose by soda, the residual lyes need not cause any uneasiness. These lyes are concentrated and then calcined to extract the alkali contained in them.

In this case the organic matter which the lyes contain partly furnishes the fuel necessary for their recovery. On the other hand, to compensate for the absence of the problem of how to get rid of these residual lyes, this process has one great drawback which explains why it is not more frequently adopted; the treatment of these residual lyes sets free very noxious fumes which, up to the present, cannot be avoided. This inconvenience and the small yield of cellulose are the reasons for the abandonment of this process in Germany. At this moment, laws are being prepared in Scandinavia, with a view to the total suppression of the noxious fumes from this manufacture, and thus the existence of the industry of making cellulose by the soda process is strongly menaced in those countries.

But the utilization or the suppression of the residual lyes are not the only important problems. Cellulose, whether obtained by boiling with alkalies or from an acid solution, must be bleached. This does not mean merely to destroy the very slight color of the chemical pulp of heated wood, but rather to carry out an operation, which is a true chemical attack accompanied by a great loss of weight (four to ten per cent in the case of bisulphite cellulose). There is no doubt that the discoloration would be much more intense and much more difficult to destroy in the case of caustic soda cellulose than it is with bisulphite cellulose. We do not know the nature of the color; besides this problem has remained unsolved in another industry, the elder sister of the cellulose industry, the manufacture of cotton, for the coloring matter which causes the discoloration of raw cotton is not clearly recognised; it is only known that it seems to act as a caustic, a destroyer. As it seems to us, instead of completing the treatment by bleaching it should be asked if the bleaching cannot be done during the treatment? Experience has taught that if the treatment is pushed too far the quantity and quality of the product are influenced to a considerable degree. The treatment should be considered as a sort of hydrolysis, so that on continuing it too long not only the lignin, but also the cellulose itself is attacked. Thus in the soda process, it must be admitted that after the solution of the compound (analogous to an ether) which is formed by the cellulose and the lignin, the lignin is changed into lignic acid by the alkali, for Lange obtained not only cellulose, but also a certain quantity of lignic acid, by fusing wood and alkali together. The theories that have been suggested as to the reactions in the bisulphite process are very diverse; whether the acid radical or the sulphurous acid remains in the state of a double salt, or whether it reacts with the aldehyde compounds, or again whether it forms ethers or sulphonated acids. The last view is one of the most accepted, thanks to the work of the Tollens laboratory; in fact, the presence of a sulphonated acid combined with the lignin, has been recognised in the residual lyes of the bisulphite process; and from this compound, though with great difficulty, by means of alkalies, a sulphonated acid has been separated at the same time as a lignic acid, apparently identical with that obtained from the soda process.

It seems to us that these considerations only concern lignin. But what can we say relatively about cellulose? Is there really a unique cellulose which is isolated when the boiling is not continued too long? Are there fixed quantities of a less stable cellulose which go into solution? It is certain that this is the case in the soda process of making cellulose; in fact the yield is fifteen to twenty-five per cent less than that obtained in the bisulphite process, and the product even after bleaching does not always appear identical with cellulose from cotton; for among other distinctions it reacts with phenylhydrazine, and forms furfurol when distilled with hydrochloric acid. Are these reactions due to the existence of a mixture of several different celluloses, or are they due to a *single* cellulose, or again are they due merely to impurities, difficult to remove? What will remain when these impurities are eliminated? It is plain, then, there is no lack of unsolved questions and that all of these [illegible]

*Translated from the *Moniteur Scientifique*

or less, await their solution by work based on experiment. But that is not all. The different kinds of cellulose formed during the boiling show still more subtle differences and present an immense field for purely chemical research, for, up to the present time, the various kinds cannot be completely differentiated by their physical properties There are certainly different kinds of cellulose pulp obtained, according as they are treated by slow boiling as in the Mitscherlich process, or by rapid boiling as in the Rittner-Kellner process.

Are all these different hydrates one and the same cellulose like that of cotton? These questions remain for the most part unanswered Only one of the questions relating to the carbohydrates has as yet received a reply It is now known, at least, that by excessive treatment of the bisulphite cellulose, a transparent substance is obtained, looking like parchment externally and quite comparable to vegetable parchment, which has been called *pergamyn*. But pergamyn is not a cellulose hydrate, but rather a cellulose boiled to the condition of boiled (sodden) rags, and from a chemical viewpoint is clearly distinguished from the hydrate, which is vegetable parchment by the reagents iodine and potassium iodide; the parchment alone, a cellulose hydrate, becomes blue

Up to now we have only spoken of wood and of the cellulose extracted from it Without going farther, other problems present themselves when the different ligneous essences are considered as subjects for research How to recognize the different kinds of wood and the celluloses they yield, the evergreen woods such as pine and fir and the wood with decaying foliage of which those chiefly used are the poplar, the birch, and the beech Every kind of cellulose produced from these different woods should be clearly distinguished

Besides wood is not the only raw material which produces cellulose Cellulose can be extracted from other ligneous fibers particularly herbaceous plants In Germany it is made from wheat and rye straw in England and in the rest of continental Europe from esparto grass or alfalfa This last can be disintegrated by a fermentation analogous to the steeping of flax, but the soda process is principally used This process only is applied to straw When the sulphate process is used i e, the process when the work of sodium hydrate is completed by sodium sulphate a forty two per cent yield of a cellulose is obtained which from its reactions should be considered as an oxycellulose although it is not as yet very thoroughly understood In spite of its comparatively weak mechanical resistance as compared to bisulphite cellulose, it furnishes a raw material very applicable for manufacturing letter paper The problem of the residual lyes is the same as in the case of boiling wood with soda Really, in the recovery of the alkali the most interesting question is that of the noxious fumes but the lyes also doubtlessly contain substances of considerable alimentary value, and further, substances which are gelatinous and have a certain coloring power, of such a kind as to offer one more reason for attempting to utilize these lyes in an advantageous manner

The considerable development of the manufacture of cellulose, both from wood and straw gives rise to the fear of a dearth of raw materials in the future Thus the German cellulose factories are already treating wood brought from the shores of the White Sea If the devastation of the forests should progress rapidly in the northern countries, the cellulose industry will be stopped by the want of raw materials There is so much the more reason that our country should be able to furnish the quantity of wood demanded by the industry Besides the available quantity of straw is very limited The indigenous plants which should furnish large quantities of fiber suitable for paper making are not at our disposal for the hope of converting turf into a fiber utilizable for paper has proved deceptive Since considerable capital has been swallowed up in attempts to effect this, it would appear prudent to give it up completely In any case there still remain reeds but only for our Austro-Hungarian neighbors In fact it seems that in the delta of the Danube and in the lower Danube region reeds are found from which there can be successfully extracted a cellulose analogous to that from straw In any case it must not be forgotten that the quantity of available fiber here is not very large Hence for the future of paper making in Germany, we must look to our colonies

For the moment let us imagine that plants could be treated where they grow, in some way so as to decrease as much as possible the dead weight for transportation, and could be sent to Europe in a half prepared condition According to information from an English origin, in Burmah alone there are 60 000 square miles covered with bamboo jungles close to navigable rivers Granting the rapid growth of these plants, it has been calculated that an area of 16 square miles would be enough to furnish the raw material necessary to make 100 tons of paper per week. It follows that Burmah, that small part of India, would alone suffice to furnish as much cellulose as the whole world demands. The scarcity of wood, however, is not yet so pressing that there is any need to introduce the cellulose manufacture in countries with a murderous climate, to consume enormous capital, and to expose it to the difficulties of considerable hand labor From this point of view America is much better off Putting aside the fact that in this country it is still possible to devastate the forests on a large scale, instead of having recourse to the creation of a new industry, the short fibers which adhere to the cotton bolls can be used, and the residues and waste of raw cotton, about 600,000 tons of raw material further there is still available about 22 000 000 tons of cotton stalks which have been hitherto considered of no value and are buried by the plow every year At the same time, and in an analogous manner, the maize stems wild hemp, marsh herbs, and wild rice are wasted Some of these American sources already feed the German paper industry Thus the factories at Bremen treat cotton utilizing the fibers sticking to the cotton bolls and using them to prepare a product commercially sold under the name of Virgo fiber (thread)

Another very important industry and to an extent closely allied to the cellulose industry has also developed greatly, that of artificial silk That, too, uses cellulose as the raw material The total natural silk in the world is estimated at 50,000,000 kilograms (110,230 000 pounds) worth $350,000,000 the production of artificial silk has reached 5,000,000 kilograms (11,023 000 pounds) worth $20,000 000 Although the use of natural silk has not yet diminished in favor of artificial silk the foregoing figures show the growing importance of this new and quite young industry; quite young for it only began in 1880

In the beginning cotton cellulose was the only thing they dreamed of using The cellulose was treated with nitric ether (*sic* nitric *acid?*), the product thus obtained was dissolved in a mixture of alcohol and ether and the solution transformed into thread which, by the use of reducing agents, such as calcium sulphide was rendered uninflammable Soon however a second process came into use, which consisted in dissolving cotton cellulose in a cupro-ammoniacal solution spinning this solution and coagulating it by means of acids or bases A third process the production of viscose silk, has lately been added to the preceding ones

But the development of this industry has not answered to its early promise on account of the high price of its raw materials, viz wood cellulose carbon bisulphide and soda lye; in fact, the manufacture is much too difficult It is only after twelve years of efforts that the scientists Cross and Bevan succeeded in making the process practical, and thoroughly mastered what they termed the "maturing" of the viscose Really when the three processes were yet in the midst of their development they encountered a fourth and most serious competitor which came on the scen although it is true that no marketable product of this process seems yet to have appeared in commerce, that is silk from cellulose acetate

While the three kinds of artificial silk mentioned earlier contained only cellulose regenerated in different ways, in this case the finished thread contained an acetic ether of cellulose This ether is insoluble in water and moreover preserves its mechanical (physical) resistance in presence of water a quality to which the other artificial silks cannot pretend except in a very limited degree The artificial silks from nitrocellulose from ammoniacal copper and viscose silk are in themselves less substantial than natural silk but when they are damp they lose a great deal of the little resistance they possess This drawback of preponderant influence has already made itself felt in dyeing but it makes itself felt still more during the weaving when the fibers come in contact with water or with damp air Silk from the acetate does not suffer from exposure to humidity At first great difficulty was experienced in dyeing because aqueous solutions of coloring matters would not penetrate the fiber but by using agents which swelled the fiber these difficulties were overcome There is no need to enlarge on this subject because a short time ago Prof Knaevenagel enlightened us as to the tinctorial properties of acetyl cellulose in a very interesting lecture with experiments that he gave at Heidelberg at the reunion of the Association of South German Chemists

All that has been previously said as to the chemical difficulties applies also to the conditions in which the acetate is produced The use of acetic anhydride and a little sulphuric acid at the same time results in the very great instability of the ethereal solutions thus obtained and this causes more or less fragility of the threads or films which have been produced Now these difficulties are avoided by various methods In Knoll & Co s patents we find sulphuric acid replaced by benzolsulphonic acid as suggested by Knaevenagel, as well as the addition of neutral salts to the alkaline salts used as regenerators The effects of these modifications are: To stop hydrolysis which is not desirable to prevent the destruction of celluloses of large molecular weight, and to obviate any ulterior modification of the physical properties of the product obtained Aside from the solution of this problem, an appropriate solvent has also been sought for several years Now acetone and acetic ether have become the regular solvents, while formerly no one dreamed of using anything but chloroform glacial acetic acid or analogous liquids, which made the practical use of cellulose acetate very difficult Thanks to the kindness of Prof Knaevenagel and the firm Messrs Kroll & Co, I am enabled to show you here some samples of cellulose acetate and of artificial horse hair the production of which is still in the experimental stage At the same time, I can show you, thanks to the kindness of the color manufacturers, Messrs Frederic Bayer & Co a fine collection of sensitive preparations with a cellite (cellulose acetate) base As you have already learned at our general meeting at Jena something of cellite films it appears that the problem of the inflammability of kinematograph films (hitherto made of celluloid) has been entirely solved

The destruction of the cellulose molecule pushed too far during the etherification referred to above is the cause of great difficulties not only in the production of acetate, but also in that of Chardonnet s Glanstroff silks, and of viscose silk which should be included in fact, during the regeneration of cellulose not only cellulose, but also a cellulose hydrate is produced This hydration must be considered as the reason for the weak mechanical resistance of the thread in the presence of water According to Eschalier this inconvenience can be avoided by treating viscose with formaldehyde in acid solution Eschalier is convinced that formaldehyde induces the spontaneous reconstruction of the molecule previously destroyed According to his figures, the mechanical resistance of viscose silk thus treated is increased in a considerable degree There still remains the question whether in spite of the increase in solidity the elongation (extension) is still sufficient for it is the low value of these two properties which has hitherto so unfavorably distinguished artificial silks from natural silks The most important problem in the industry of artificial silks that still remains to be solved is that of endowing them with these two properties

There is still to be mentioned the complication of questions relating to cellulose hydrates found in Knecht s recent work on mercerized cotton He shows that the absorbent powder of cotton differs remarkably according to whether during mercerization it has not been dried at all or has been dried and if dried whether this has been done at the ordinary temperature or at 100 deg C (212 deg F) Hence different methods of drying give rise to different hydrates Also Berl states that if cotton is heated in a current of inert gas at a high temperature, it undergoes polymerization which exerts a favorable influence on the properties of the resulting nitro celluloses

These considerations make it sufficiently clear that in the cellulose industry and its allied industries in spite of the numerous isolated observations the characteristics of cellulose or the celluloses are very imperfectly known from the chemical point of view We do not even know the constitution of the cellulose of cotton which may be taken as the type and still less of its derivatives— the cellulose hydrates the hydrocelluloses and the oxycelluloses We can only form a vague idea of these bodies If the cellulose industry is to continue to progress, it is absolutely necessary that a systematic study be made of all the bodies included in the above category

An advance in the study of their constitution can generally be effected either by the synthesis or the analysis (destruction) of these bodies There can be no question at present of constructing a molecule of cellulose, but by destroying an apparent molecule, a certain enlightenment seems to have been obtained By making decomposition products we have only a very superficial idea of the celluloses hydrates but we already know a little more about the hydrocellulose we specially know thanks to Tollens that when the oxycelluloses are heated with milk of lime (calcium hydrate) they yield dioxybutyric acid and isosaccharic acid, we know that they form sugar by hydrolysis in an acid solution and by the same method a body representing an intermediary state of transformation between sugar and cellulose—cellobiose

The theory based on the figures representing these decompositions would be very fruitful and would be still more so if the researches were made under similar conditions on the large number of celluloses that can be isolated from wood and herbaceous plants It is highly probable however that resort must be had to new methods of research The future will tell us if these new methods should to some extent encroach on the boundaries of the chemistry of the colloids In spite of the successful results found in the domain of the chemistry of the inorganic colloids it seems as if the organic colloids, cellulose among them would escape from disclosing the secrets of their constitution like so many colloidal substances Whether it be by purely chemical methods, or by physiochemical methods there is no doubt in any case that those who devote themselves, regardless of the labor, to such serious experimental researches will have greatly accelerated the progress of the chemistry of cellulose as well as that of pure science and that the progress of the cellulose industry will likewise be facilitated

Additional Points about the New Paris Subway

We are able to give some additional points about the new Paris subway which has been lately opened. At one of the terminal stations there has been installed a very complete system of switch and signal control This is necessary from the fact that the subway does not make a loop and the trains need to be shifted to the return tracks Besides, there are other tracks laid which lead to the station yards near by, so that here there are used in all seven tracks Switches and signals are worked by Taylor electric motor devices, and their circuits come to a central operating switchboard. On the board is a reduced plan of the whole plant, with pilot lamps and indicators, so that the electric operating switches can be worked to suit the case There are 19 interlocking levers used in all. The motor cars carry Vedorelli double pantagraph trolleys with rubbers of special alloy, one on each end of the roof, and these work under the trolley wire which is mounted on brackets with 60 feet average span The third rail weighs 60 pounds per yard, and is supported on stoneware insulating blocks which are found to be moisture proof For connecting, the front car motors are joined to the trolley and the grounded track rail, and the rear car motors from third rail to track rail, on the three-wire system, using 600 volts on the motors or 1200 volts in all The substations contain four special rotary converter groups of 1,500 kilowatt size fed by alternating current from a bank of 1600 kilowatt three phase transformers The groups supply direct current at 1,200 volts for the subway circuits A storage battery furnishes an extra lighting circuit which runs through the subway as a standby Metallic filament lamps are used in the subway, and carbon lamps in the trains Improvements are made in the block signals so that the trains are never stopped in the tunnel, but can always run into a station provided this is clear and passengers can thus leave the train in case of accident that may arise from various causes.

Modern German Police Call and Fire Alarm Systems

Some Recent German Designs

By Frank C Perkins

Every modern fire department and police department must have a trustworthy call and alarm system An effective and reliable call and alarm system is as necessary as an efficient police equipment or effective apparatus at the fire itself The accompanying illustrations show the construction and method of operation of modern fire alarm systems of German design and construction and police station equipment in the city of Rio de Janeiro Of the accompanying illustrations Fig 1 shows the switch board and receiving apparatus at this installation while Fig 2 shows the relay table and illustration Fig 3 the master clock utilized in connection with the recording mechanism of the calls sent in from the various boxes The diagram Fig 4 indicates the circuits connecting the alarm boxes with the various station houses as well as with the central station There are from 5 to 15 alarm boxes in each circuit connecting with the receiving apparatus at the station

At Rio de Janeiro there are a total of 580 call boxes connected in circuits as indicated special boxes mounted on posts being provided with telephone equipments for communicating with the various stations and with head quarters The turning of the key in the door of the box sends in the call automatically to the station, the number being recorded on a section of the tape as indicated in drawing Fig 5 together with the date, giving the year month and day as well as the hour minute and second when the call was sent in

The switchboard equipment alarm boxes and electrical connections as utilized at Essen and Ruhr and other cities and towns in Germany are shown in illustrations Figs 6 10 The station equipment at Essen is shown in Fig 6 the design of the alarm box in the city being noted in Fig 7 The fire station equipment of smaller towns may be seen in illustration Fig 8, including the receiving apparatus the alarm gong in the station and telephone equipment as well as the alternating-current bell ringing magneto for calling the firemen from their homes in various sections of the town Fig 9 shows the construction of an alarm box for a small city while Fig 10 shows a more elaborate equipment for larger cities

Everyone is familiar with the electric house bell The current traverses the circuit only for a moment in which it does its work Such a system is called an 'open circuit system With house bell installations, failures of the current or defects are not evident until one attempts to use them An open current installation therefore is useful only for fire alarm systems under limited conditions

When this arrangement is reversed the current is allowed to flow steadily through the circuit and as soon as a signal is given the metallic circuit is interrupted In such a system any interruption of the current due to a break in the current will without any aid sound the alarm signal Thus we obtain the desired automatic control in a very simple way As in this method the current is always flowing during the normal condition of the installation it is called a "closed circuit system" This method of operation is used in all modern fire alarm installations

A closed circuit for interrupting the current with push buttons is the simplest kind of a fire alarm system In such push button installations one could of course without further equipment make the alarm-sending point distinguishable at the central by having the button simply releases a spring clockwork placed within the alarm box The clockwork then rotates a metal disk having a toothed edge The disk is brushed by a spring-metal strip, which when at rest, presses continually against the contact screw The current flows through the spring brush to the contact screw and as soon as the turning of the disk allows the brush to fall into a slot,

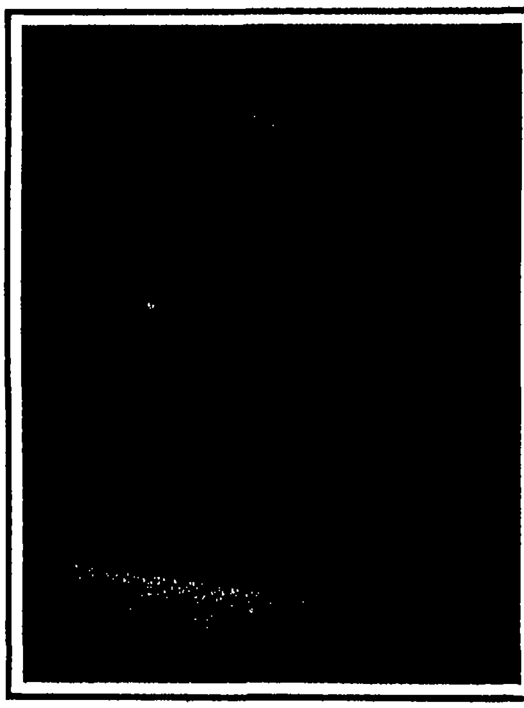

Fig 2—RELAY TABLE OF RIO JANEIRO INSTALLATION

the metallic contact between the brush and the contact screw is broken thereby sounding the signal at central When the brush has passed a slot the circuit is again completed and in accordance with a number of slots a particular number of current interruptions is produced Therefore the disk alarm box No 1 has one slot, that of say alarm No 8 has eight slots, it therefore allows that it must be simple to make the number of the particular alarm box recognizable at central In practice the disks in the different boxes not only differ as to the number of teeth but also as to their size and their spacing on the disk; in fact they are so arranged that the disk can send regular Morse signals to be recorded at the central station

Moreover it is possible to put as many alarm boxes as desired on a single line for as each alarm box has a different numbered disk no errors can occur Upon receiving an alarm at central it merely remains to look up the number on the register which shows the place from which the alarm was sent The circuit starting from the central station is run through all the alarm boxes in means of a special rubber washer The importance of this is very evident, as fire alarm boxes are usually in the open and constantly exposed to the weather The clockwork would suffer so much through dust, moisture and oxidation that reliable operation would soon become questionable, particularly as in small installations there is usually no skilled labor available to attend to the inspection of the boxes For the same reason the contact arrangement of the clockwork is constructed with particular care, in fact, for reasons of safety, the most important contracts are provided in duplicate The clockwork case is set in a red japanned outer cast iron case.

Large and elaborate alarm boxes are used for large cities as seen in illustration Fig 10, but are usually too costly for small installations Inside of the box, in addition to the clockwork with a case, is a lightning protector and contact key The key is employed by the firemen for special purposes in calling the central station In the front door is the push button, covered by a thin glass pane the only part of the signal sending mechanism accessible to the public Signal sending by pressing a button was intentionally chosen, as everyone is familiar with the push button which is widely used. The glass pane, about 1/64 inch in thickness, can be easily broken by a light blow

It has been found that covering the push-button by a glass pane has proven the best means of preventing the ringing of false alarms An uncovered handle or push-button would directly tempt mischievous or malicious misuse Moreover the use of the glass pane has the advantage that legal punishments for the wrongful misuse of an alarm box become more severe (the breaking of the glass being a damage to property) than it would be for the simple misdemeanor of sending a false alarm

In some German fire alarm systems in order to reduce the misuse as much as possible and make it easier to catch the malefactor, a loud ringing mechanical vibrating bell is often put in the door of the alarm box Pressing the button here releases both the alarm mechanism and that of the warning bell, which latter rings for a certain length of time and then stops of its own accord. It serves the purpose of calling the attention of nearby residents and of passers-by to the fact that some one is sending in a fire alarm This arrangement has proven very satisfactory It is not necessary to provide all the alarm boxes with bells Usually only those located in the residence section require them

As a receiving apparatus for small systems the direct indicating apparatus has proven itself very reliable. The indicating apparatus noted in Fig 8 contains, in back of a locked glass door a signal annunciator disk and a line relay transmits the incoming signals to the actual indicator or pointer system the dial of which shows the various alarm box numbers For practical reasons not more than 16 or 20 alarm boxes on one circuit are connected to one indicator If there are more alarm boxes or circuits a second indicator is required in addition to the first

When the glass of an alarm box is broken and its clockwork released the signal annunciator disk at the central station falls, the pointer moves—following the current interruption by the alarm box clockwork—and remains stationary at the number of the sending box. At the same time an alarm bell rings and continues ringing until someone has raised the annunciator disk and by

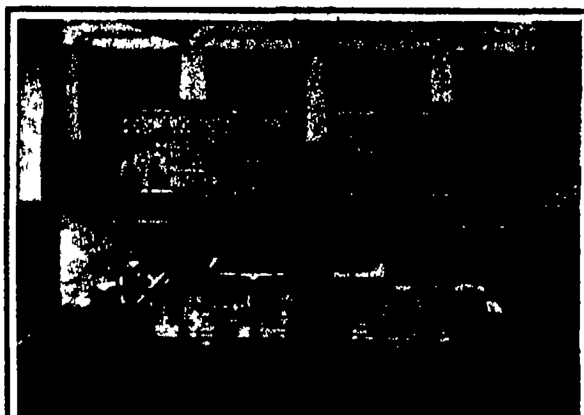

Fig 1 SWITCHBOARD AND RECEIVING APPARATUS AT THE INSTALLATION OF THE CITY OF RIO JANEIRO

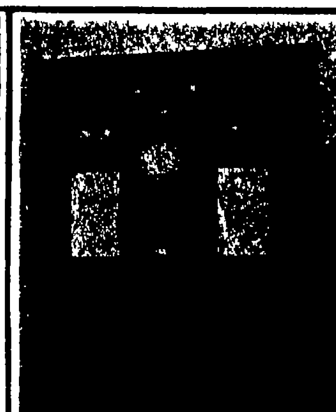

Fig 8—FIRE STATION EQUIPMENT OF A SMALL TOWN

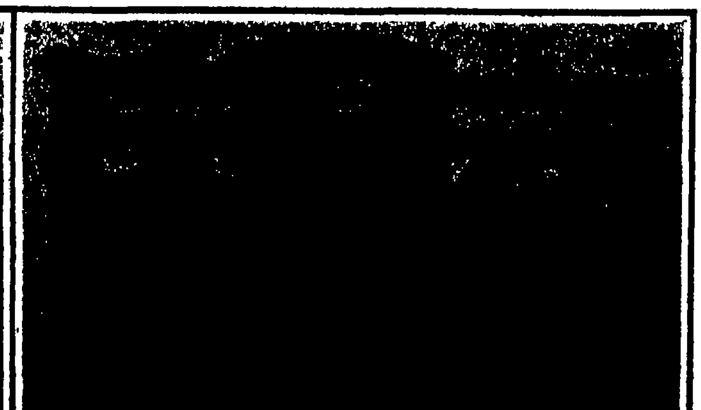

Fig 6—STATION EQUIPMENT OF THE TOWN OF ESSEN, GERMANY

pressed once at Station 1 twice at Station 2, and six times at Station 6 but in the excitement mistakes are unavoidable So it becomes evident that the interruptions of the current to denote the number of the sending point, instead of being controlled by hand, should be automatic.

A German device of this kind is operated as follows, and indicated in Fig 9: The alarm sender does not directly interrupt the current by pressing the button, but the city and then back to central. This is called a series circuit" or loop For practical reasons not more than 20 alarm boxes are put in one loop, a second loop entirely independent of the first being run as soon as more alarm boxes are added to the system.

It will be noted that the clockwork of the fire-alarm boxes of German design is mounted on a cast iron plate, placed in a small case and made absolutely waterproof by pressing a lever has brought the pointer back to its initial position.

In small cities the receiving station is situated at some suitable place as the City Hall, the police headquarters or the fire engine house where some one is always stationed at night, who, after receiving an alarm can reset the indicator apparatus and arouse the firemen. The alarm must be heard because of the continuously ringing

loud alarm bell. The person left in charge of the station over night can go to sleep, and be sure of being awakened by the alarm.

In larger cities where there is a regular fire department, or a small force of firemen is always kept in readiness, the men can go to the indicator alarm box immediately after receiving the alarm. However, if there is in addition a volunteer fire department or, in fact, only such exists, they must be informed upon receiving the alarm. This can be done in many ways by means of steam whistles, fog-horns and bells. In modern systems, however, a public general alarm is generally avoided, as it causes unnecessary excitement, particularly at night. Hence, *preference is given to the so-called private alarm*, i e., alarm arrangements, which, at the breaking out of a fire, summon only those persons who belong to the fire fighting forces.

It is maintained that for private signals for the firemen the use of alternating current alarm bells is best suited, the bells being put in the homes of the firemen If the bells are connected in separate alarm lines, they must be connected in a closed circuit. The current steadily flowing through the circuit does not affect the alarm bells To ring them the necessary alternating current must first be generated at the central station This is done simply by turning the crank of a magneto As the bells ring only so long as the magneto is being turned, it is possible to give various signals by varying the turning of the magneto crank handle.

It is stated that about 30 alarm bells can be rung at the same time by the magneto As soon as more bells are to be added, the fire-alarm box circuit, by leading back to the central station several times, can be divided into a number of alarm bell loops Each of these alarm bell loops has its contact key on the magneto The individual alarm bell loops, *in each of which there may be up to 30 bells*, are operated simultaneously but one circuit after another This subdivision into several alarm bell sections has the advantage of notifying only those located in that section in which the sending alarm box is, and then later the others, if the men already at the fire are not sufficient.

Usually the magneto, together with the indicator apparatus, is mounted on a wall switchboard, on which there are also placed the auxiliary apparatus, including the lightning protectors, which protect the sensitive parts of *the receiving apparatus not only against lightning strokes* which directly strike the overhead wires, but also against weaker atmospheric discharges and against heavy current discharges in case the overhead lines come in contact with street car or other power circuits

There is also in some instances on the board a list of the alarm box numbers with their respective locations, directions for the operators and two bells which ring during an alarm, for the control of the signals sent off If there are two indicator apparatus, a similar board is used in larger installations having three or more indicator apparatus, *correspondingly larger switchboards are used*

The battery cells necessary for operating the system are also placed at the central station in a locked closet or cabinet For generating the direct current in the box circuits, closed circuit cells are used these having an electrolyte of copper sulphate; they are recharged about two or three times each year For controlling the battery an ammeter is provided in the indicator apparatus, which shows the current flowing through the line

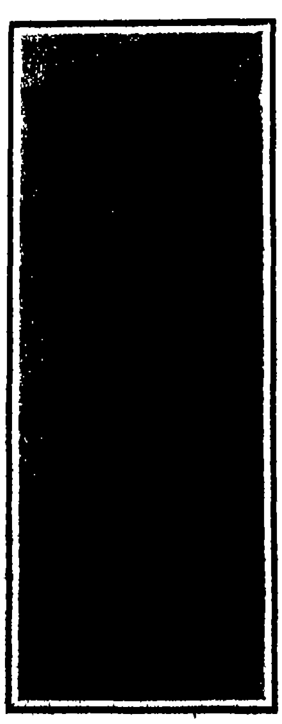

FIG. 3.—MASTER CLOCK

in the local or annunciator circuit Leclanche or dry cells are used.

As indicated in the illustration the switchboard and the battery cabinet together constitute the complete central station of a fire alarm system and are easily installed

In case electric power is available in the city, small storage batteries are used instead of the primary cells. The storage batteries, if small in number, are placed in closets provided with a chimney to allow the gases which develop to exhale, or in larger installations are put in the cellar on stands of several tiers. Operation with storage batteries is more convenient and cleaner The cost is greater, but the operating expenses are lower with primary cells. The switchboard required for the monthly charging of the storage batteries, is very simple and can be operated by inexperienced persons.

Fitness in Machine Design

IT is commonplace that, in the design of any new machine, or structure, the relative proportions of the various parts, and their positions in relation to each other, are determined rather from precedent and experience than by calculation Certainly, in simple cases calculation may be employed, and is employed thus, for instance the

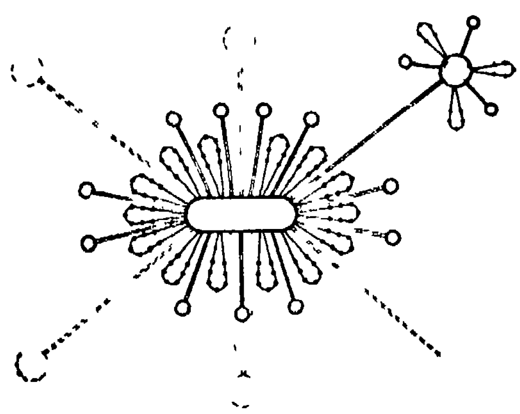

FIG 4—CIRCUITS CONNECTING THE ALARM BOXES

dimensions of a simple tension member of a bridge may be directly determined from the known properties of the material from which it is to be made although even in this case, the factor of safety to be employed is fixed in terms of precedent and experience alone In general in simple structures, a mathematical determination of the dimensions of parts may be employed but as they tend to become more complicated the reliance on precedent and judgment becomes ever greater In the design

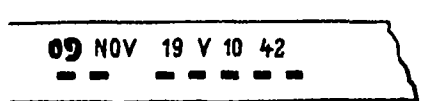

FIG 5—REGISTER ON TAPE

of machines this reliance on personal judgment becomes still more noticeable Even here, however some few leading dimensions may more or less, be determined mathematically the diameters of shafts and the sizes of bearings may for instance be so fixed although these will frequently be modified by a designer in order to bring them into what he considers better relation to the general arrangement and dimensions of a machine which are of

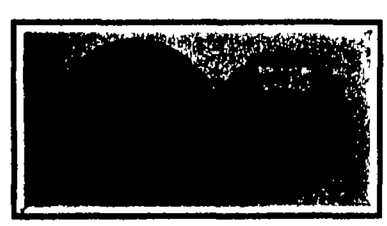

FIG 9—ALARM BOX OF SMALL CITY

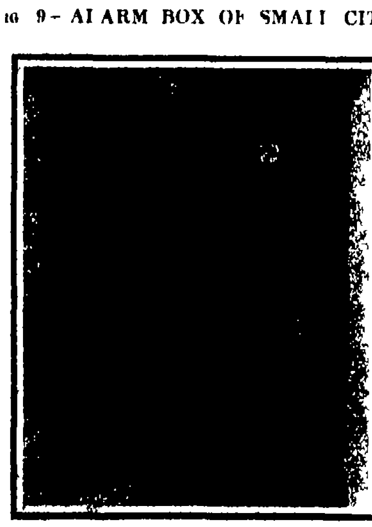

FIG 10.—ALARM BOX FOR LARGER CITIES

course, a function of the operation it is intended to perform. Allowing, however, for cases in which calculation is of assistance in general, it may be said that the determination of the dimensions of machine parts is a process depending rather on experience and individual judgment than on mathematical considerations

The ability to determine instinctively the correct dimensions for a machine part which is to be subjected to indeterminate stresses is a common enough feature among machine-designers. All competent draughtsmen have it in greater or less degree It has even received a name, and those in whom this ability is strikingly displayed are commonly said to have a "mechanical instinct." The system on which this ability operates, and by which such instinctive designing is carried out, is worth a little attention It is common practice to sketch out roughly the general lines of a new machine on a drawing board, and to determine approximately the sizes and shapes of the main parts from this sketch, various dimensions, curves and tapers being modified in freehand until the whole begins to hang together properly and the different parts bear such relation to each other as to make the whole appear a satisfactory and workable and probably a neat machine The process is largely a visual one and although there are men capable of forming wonderful mental pictures of new machines or apparatus, even they will, in general be found more or less to modify their ideas when they see them down in black and white The dependence of this process of instinctive designing on the visibility of the object designed is a matter of some interest, and may be given a little consideration.

The fact that the mechanical instinct judges the soundness or otherwise of a design by its appearance may be interpreted by saying that such instinct is but an example of visual memory and that the eye after long training and familiarity with correct designs, retains a sort of standard with which it is capable of comparing future examples which may be presented to it. This however appears a somewhat limited statement of the case, as a sound designer is capable of correctly proportioning the parts of an entirely new form of machine or of one of a type with which he is not familiar It would probably be nearer the truth to say that the actual appearance of a machine and the general look of fitness of its various parts in relation one to another is in fact a direct measure of its efficiency as a piece of mechanism In one sense, of course this statement is a mere truism but the present idea goes further than the first obvious meaning of the sentence and suggests that the mere general appearance of a machine is, in fact, some measure of its adequacy as a machine The idea is that there are certain *more or less obscure principles of fitness or if one* prefers it of beauty to which correct design of necessity conform and that competent designers work in terms of these principles without necessarily recognizing their existence or being able to state them This idea is but a particular application of a doctrine which in one form or another has been advanced times without number in relation to the Arts the doctrine that the best and finally correct form of anything is at the same time the most satisfactory in appearance—the most beautiful This was one of Ruskin's favorite doctrines and there *would be no difficulty in finding a dozen passages in his* works illustrating it For instance: Few buildings are beautiful unless every line and column of their mass have reference to their foundation and be suggestive of its existence and strength so nothing can be beautiful in Art which does not in all its parts suggest and guide to the foundation Translating this into engineering language one may say that of two machines that will be the best mechanically which is the best in appearance and which the proportions and relations of the various parts suggest to a competent observer a proper distribution of weight and stress The classic expression of this doctrine of fitness and efficiency or beauty and truth as Ruskin would call it is due to Keats:

"Beauty is truth truth beauty—that is all
Ye know on earth and all ye need to know

FIG 7—A CITY ALARM BOX

It may appear a far cry from Keats to machine design and yet it is probable that if this doctrine is not pushed too far it will be found to have quite definite application in practice.

This matter cannot be satisfactorily discussed without a consideration of what constitutes fitness or beauty in machine design, although, by approaching the matter from this point of view there is some danger of reasoning in a circle In the early days of the development of the steam-engine and machine tools it was the prac-

tice to attempt a sort of added beauty in mechanical constructions by such devices as the provision of Corinthian pilasters on engine standards and the adornment of bridge work with various species of cast iron carving. This type of engineering art found little favor with the professed experts in artistic matters and there is an amusing story told, if our memory serves, by Sir Benjamin Baker to the effect that in his early days he had adorned one of his bridges with some type of cast iron filigree work which drew from Ruskin the remark that the sight of it always made him wish he had been born a blind fish in an underground cave, and thus escaped the pain of ever seeing it. This system of designing a machine, or structure and afterward sticking on a certain amount of external decoration endured later in the United States than in Great Britain, but although it still crops up at times it is fairly generally abandoned nowadays. We recently came across a water meter intended for irrigation or similar use which was carried on a pair of cast iron legs of floricultural design that were appropriate rather for a German beer garden than an engine room. Examples of this order are, however, rare at the present time, and whether it be as a result of criticism by engineers themselves or that of outsiders, there is no doubt that the majority of designers are now persuaded that any beauty in mechanical work must inhere rather in the lines and proportions of the design than in added matter of any description.

It may appear that a conclusion to the effect that external decoration is unsuited for mechanical constructions and that beauty in such works can be obtained only by a proper distribution of forms and proportions merely leads back in a reverse direction to the point we attempted to attain in the early part of this article. There is, however, a difference in the conclusions reached by the two ways of approaching the matter, which may perhaps be illustrated by an example. A good deal of criticism has at one time and another been directed against the Tower Bridge on the score that its ornamental features are purely extraneous, and that the masonry towers form no essential part of the design but are simply added to make the bridge look "pretty," the implication being that had the steel work been left in its nakedness without covering of any sort, the final effect would have been more beautiful. This point of view assumes, or should assume, that the steel work is of bold and straightforward design admirably suited for its purpose, and such that in it the general distribution of weights and stresses can be followed by a trained eye. This represents the anti-decoration point of view which was considered immediately above. The alternative way of looking at the matter, however, which we dealt with first, asserts that had the steel work been left bare, then the general impression of beauty which it conveyed to the eye of an engineer would actually be a measure of the mechanical adequacy of the design; and that a construction which, although satisfactory and workable enough, yet was more or less disproportionate or wasteful of material, would, for that reason, appear less beautiful and fitted for its purpose. It is clear that a full discussion of this matter would involve an inquiry into the nature of beauty but that investigation has bogged too many generations of philosophers to be attractive, and the meaning attaching to beauty or fitness, in machinery is in general, quite sufficiently understood for our purpose.

We have no wish to suggest that the idea of fitness of appearance or beauty, in a piece of engineering work being in some way consonant with its mechanical adequacy is capable of anything more than very general and loose application, but none the less we think the idea will be found to have a sound foundation. It is not difficult to find examples to illustrate the matter. A very simple one has reference to the distribution of weights. A tower crane, for instance, with a revolving hammer head that is designed with such insufficient counterweight that serious and unintended stresses come on the center bearing will to a trained observer, look wrong at the first glance. It may take a few minutes for him to decide what is missing or what is wrong in the relative proportions of the parts; but he will at once see that there is a defect somewhere. The crane will look wrong and the suggestion is that it will do so because it betrays certain principles of fitness which are essential in a machine if it is to look right. Another example which may be quoted is the case of a heavy machine tool in which the legs are so light that excessive vibration is bound to be set up when the tool is operated. In this case, again, the machine would look wrong at first sight, to a trained man, simply because its design would be at variance with principles of correct construction, which are a part, possibly an unconscious part, of the observer's mental equipment. There is no need to multiply examples to illustrate this idea, but, it may be pointed out, that even such small matters as the *rounding-off of the edges of castings appear to be* consonant with the "beauty is truth" doctrine. Square-edged castings not only look wrong, but are wrong. A fine example, which is of some interest, may be mentioned. We believe attention has been drawn to it by Mr. Lanchester. It has reference to the position of the steering hand wheels of motor cars. In the early days it was the practice to carry such hand wheels on vertical spindles, so that they lay in a horizontal position; while at the present time it has become practically universal custom to incline the spindle toward the driver's seat, so that the hand wheel also occupies an inclined position, which in high-speed cars usually approximates to about 45 deg. from the vertical.

This change has come about partly as a result of the increase of the length of the cars; but the question of appearance has also had weight, and there is no doubt that not only designers, but the general public also, consider the inclined position the most fitting and the most in keeping with the lines of the car. One obvious reason for this is that the inclined position of the spindle adds to the impression of speed which is rightly inherent in the build of motor cars, especially heavily powered ones. It is interesting that this change, which is in every way sanctioned by æsthetic considerations, is directly substantiated by mechanical ones. With a steering hand wheel in a horizontal position, the effect of the inertia of the body of the driver, when the car is rounding a curve, is to tend to make him move the wheel farther round than he intends, so that defective steering results. This point is of much importance in high-speed cars. As the steering wheel approaches more nearly to a vertical position this inertia effect is more and more eliminated, so that the inclined wheel not only looks better, but is actually mechanically better, as conducing to easier and more accurate steering.—*Engineering.*

Value of Illuminating Engineering to the Manufacturer*

A New Art and Its Possibilities

By V. R. Lansingh

The different classes of manufacturers who are engaged in supplying things necessary for artificial lighting and who are directly benefited by the subject of illuminating engineering may be roughtly classified as follows:

A. The manufacturer of artificial illuminants.

B. The manufacturer of shades and reflectors.

C. The manufacturer of appliances used with artificial lighting.

D. The manufacturer of contributing apparatus, that is to say, apparatus which is necessary finally to produce artificial light.

E. The manufacturer of electricity or gas; for example, the central station or the gas plant. This last class is covered in convention papers by Messrs. Serrill and Gilchrist and consequently will not be considered here.

Taking up the first class; namely, the manufacturer of illuminants, this can be divided into four sections, namely, electric, gas, acetylene, gasoline. In the scope of this paper it will not be necessary to analyze the value of each of these divisions separately, but they can be considered as a whole.

A. BENEFITS TO THE MANUFACTURER OF ILLUMINANTS.

The products put out by the manufacturer will be used more correctly and consequently will give better satisfaction, which will lead to their wider use.

By a knowledge of illuminating engineering new fields for the manufacturer will be opened up.

A knowledge of illuminating engineering will teach the consumer to choose correctly the character of illuminant desirable for the work in hand which will lead to a wider extension of such illuminant for such work.

Illuminating engineering improves the quality of the manufacturers' product.

Illuminating engineering teaches the salesman of the manufacturer to solicit business intelligently, placing him in a decidedly advantageous position over his competitor who has not this knowledge.

It puts the manufacturer employing such methods above his competitors not employing them, making it, therefore, more easy to sell his goods.

These advantages may well be discussed more in detail. One of the greatest complaints of the manufacturer of illuminants is that the public does not use his product as it is intended to be used, and consequently the customer does not get the satisfaction which he was led to expect from the manufacturer's statement. Thus in the case of the incandescent electric lamp, the customer orders a lamp of 110 volts when perhaps he should have ordered one for a 105-volt circuit. The result is dissatisfaction and results in the loss of future business to the manufacturer supplying the lamps. In the case of the yellow flaming arc lamp it is sometimes seen in front of a store window where the storekeeper is attempting to show color values. The bad results consequently obtained may lead to the condemnation of the lamp simply because it was used in the wrong place. A notable example of this was the use of the mercury vapor lamp in its early days in many places where it should not have been employed with the consequent condemnation of the lamp which greatly retarded its introduction in such places where it was entirely suitable. Similar examples might be cited in other fields, but those given will probably make the point clear.

It is self-evident that a knowledge of illuminating engineering opens up new fields which heretofore were unavailable. For example in automobile head lamps the field was almost entirely in the hands of the acetylene industry until by the introduction of illuminating engineering principles (illuminating engineering is here used in its broadest sense) the manufacturer of electric appliances has been able to compete successfully. This condition required a thorough knowledge on the part of the manufacturer not only of the manufacture of a suitable lamp and the proper length, shape and position of its filament, but also the use of it in conjunction with the proper reflector with an adjustable method of focusing. Had not all of these combinations been properly employed the field would have been closed to the manufacturer of the incandescent electric lamp. It is exactly along similar lines that the acetylene industry has gained such a hold in automobile lighting as compared with the lighting by means of oil lamps first employed and still adopted on many automobiles.

In the industrial field it is found that knowledge of illuminating engineering is of the utmost importance to the manufacturer of electric illuminants, as is evidenced by the fact that one interest has devoted some $50,000 toward making investigation as to the requirements and the methods of solving the problem of industrial lighting. Before the manufacturer can hope to invade such fields he must make a thorough study of all the conditions, such as the placing of the units, the size of the lamp, the height above the floor, the color of the light, and many other problems which can only be solved by a thorough study. Examples of the benefits to be derived by the manufacturer in the study of these problems might be multiplied many times, but one other example will suffice. In the field of street lighting the old open direct-current arc lamp giving the maximum candle-power at 45 degrees was almost universally employed in the early days of electric street lighting. A careful study of the problem showed that these lamps were far from being ideal for street lighting, and a thorough study of the problem, which is still being continued, has shown that illuminants of different characteristics are desirable, and there has therefore been introduced for such work the inclosed arc, the magnetic arc, the flaming arc, as well as different forms of incandescent electric illuminants. In the case of gas street lighting, the old open flame burner has been almost entirely superseded by the mantle burner, either singly or in clusters, as for example the high power high-pressure incandescent gas mantles used for lighting many of the cities of England and the Continent. It was only by a knowledge of the distribution and character of the light that the manufacturer has been able to introduce his product against the competition of the older and more firmly established illuminants.

A knowledge of illuminating engineering improves the quality of the manufacturers' product. The manufacturer who would improve his product calls to his aid many of the different branches of illuminating engineering, using this term in its broadest sense. He calls upon the chemist, the physicist, the glass maker, the shop process man, the selling organization for their experience in things desirable and by means of all of these the product is gradually raised in quality, due to the wider knowledge of illuminating engineering. For example, in this country the quality of the incandescent carbon lamp has gradually been raised so that to-day a lamp of from 2.5 to 3 watts per candle is obtainable, where formerly for the same length of life a consumption of from 3 to 3.5 and even 4 watts per candle was necessary; while in England, where little is as yet known of illuminating engineering, and where commercial methods have not the same tendency to advance it as they do here, the lamps reach as high as 8 or even 10 watts per candle, resulting most disastrously to the introduction of electric light in competition with gas. Summing up, therefore, it may be safely stated that one of the greatest values of illuminating engineering to the manufacturer is the resultant improvement in the quality of the illuminants he makes.

It teaches the salesman to solicit business intelligently, and a salesman equipped with a knowledge of illuminating engineering cannot be placed in the same class as one without this knowledge. This is so well recognised to-day that the trained illuminating engineers who also have selling ability command the higher salaries and are of far greater value to the manufacturer than those without this knowledge. This condition is so rapidly increasing that with the growing knowledge of illuminating engineering among the buying public, the companies whose salesmen have been best educated in illuminating engineering are those who are making most rapid progress.

In a like manner it puts the manufacturer using illuminating engineering above his competitors who are not employing such methods, for the manufacturer is, after all, nothing but a salesman, and what is true of the salesman is also true of the manufacturer. This is well evidenced by the recent rapid progress made by the manufacturers of incandescent electric and gas illuminants who have made illuminating engineering departments part of their regular organisation.

B. BENEFITS TO THE MANUFACTURER OF SHADES AND REFLECTORS.

To the manufacturer of ordinary glass shades which are designed primarily for decorative or diffusing purposes, a knowledge of illuminating engineering is of value. As an example can be taken the question of the color of illuminants and its relation to the glassware

* A paper presented at the Fourth Annual Convention of the Illuminating Engineering Society, Baltimore, October 24 and 25, 1910.

used. Thus if a glass manufacturer wished to obtain a glass for home lighting which would give a warm color to the eye, but at the minimum loss of absorption, he would employ a different glass for tungsten lamps from that he would use with carbon, since in the latter case it is not necessary to employ as much color as in the former. Similar examples of the value of illuminating engineering to other branches of ordinary decorative glassware might be easily multiplied, especially in the physiological and psychological effects it is desired to produce.

In discussing, however, the subject of reflectors, it is at once evident that a thorough knowledge of illuminating engineering, not only in its broadest sense but in its more narrow and usual application, must be employed. Thus, in the case of prismatic reflectors, there are all sorts of candle-power distributions which have been obtained to fit different conditions, as for example the so called "extensive" "intensive" and "focusing" forms of distribution, all of which have been designed to fulfill lighting conditions which it would have been impossible to produce or even know the requirements of without a proper knowledge of illuminating engineering. In fact such glassware is, as a rule, designed after the requirements have first been laid down in accordance with the principles of illuminating engineering. It is self-evident that new fields are being opened up from time to time by a study of the requirements through the aid of illuminating engineering. The same careful work is not only being done in the case of prismatic reflectors but also with other types; for example in the case of a type of reflector designed to give a symmetrical distribution throwing the light up and down the street which was designed after a study of the requirements had shown the necessity for a very broad candle power distribution in which the flux of light was largely confined to the street rather than spread uniformly into surrounding space. In the case of indirect lighting there is another example where by careful design distribution curves have been obtained which will give maximum efficiency for this system of lighting. As a matter of fact, the proper design of reflectors could hardly be said to exist were it not for a proper knowledge of illuminating engineering and these two must of necessity go hand in hand. It is for this reason probably that the manufacturers of shades and reflectors were the first to recognize the value of illuminating engineering, and they have done all in their power to spread the art among the public as well as among those directly interested.

C VALUE TO THE MANUFACTURER OF APPLIANCES.

Under this heading can be included all those devices which are directly applicable to the illuminants themselves. Thus, there are the fixtures used to support the illuminants and their shades or reflectors, the burners in connection with mantle gas lighting; the sockets for electric lamps; the tips for open gas and acetylene lighting, as well as numerous other appliances. The fixture manufacturer has been generally speaking slow to recognize the value of illuminating engineering as applied to his art; but to-day the most progressive houses are recognizing its value and are accordingly taking advantage of it much to their financial benefit especially in commercial lighting. The lighting of a great majority of stores office buildings and other commercial places is to-day being done by units which are properly supported by fixtures designed to give definite results. This is equally true of both gas and electricity. The result has been that within the last five years the types of fixtures for lighting such buildings and places have been entirely revolutionized and those manufacturers who do not take advantage of the knowledge of illuminating engineering necessary to obtain the desired results must of necessity fall behind in the race. Even in the case of more decorative plans where efficiency is of secondary consideration a knowledge of illuminating engineering is beginning to tell. In the home to-day for example the educated customer is beginning to insist that his house shall not only be properly lighted from an artistic standpoint, but also from an economical and physiological standpoint and the manufacturer who can take advantage of these conditions is the one who will get the business. It will therefore be evident that a knowledge of illuminating engineering in the proper design of fixtures to fit the conditions at hand is also of value.

In the case of burners for mantle gas lamps the question of price is of secondary consideration. This is evidenced by the fact that the majority of the business of the country for this line is controlled by one company; this is due to the quality of its apparatus rather than a question of price. Such burners being designed along scientific lines and with the ideas of illuminating engineering used in its broad sense have become standard for this class of work throughout the country. The fact that the company above mentioned is employing illuminating engineering methods and is the foremost one in the gas field fully bears out the point mentioned.

A similar line of argument might be used in the case of acetylene burners, sockets and other material directly used in support of illuminants; but sufficient has been given here for the purposes in hand.

D VALUE TO THE MANUFACTURER OF CONTRIBUTING APPARATUS

The value to this class of manufacturers is indirect rather than direct but that its value is great no one would deny. Thus in the incandescent electric lamp field the extension during the past few years into new fields has been tremendous all of which means a larger demand for apparatus of all kinds. The manufacturer of the electric generator the steam boiler and all the other necessary parts to a generating station conduits, wire porcelain and all the appliances necessary for the distribution of electrical energy have been greatly benefited by the large increase in the use of electric energy by reason of a more thorough appreciation of its advantages by the public which have been largely caused by the correct use due to a knowledge of illuminating engineering either on the part of the customer or those responsible for the sale of the illuminants. That this is of great practical value is recognized by the great electrical jobbing fraternity of the country who when asked by a prominent manufacturer whether they would rather have a larger margin of profit and have the educational work in illuminating engineering by the manufacturer cease or have their present margin of profit with the educational work in illuminating engineering continued stated that owing to the large increase in sales of contributing apparatus as well as the direct illuminants and their accessories they would much prefer to have the missionary work in illuminating engineering continued.

CONCLUSIONS

It is seen from the examples cited above that illuminating engineering is of great benefit to the manufacturer of all sorts of apparatus used in connection with artificial lighting either directly or indirectly and the fact that large sums of money are being spent to further the knowledge of illuminating engineering is ample evidence of the correctness of this statement.

RULES GOVERNING THE COMPETITION FOR THE $15,000 FLYING MACHINE PRIZE OFFERED BY MR EDWIN GOULD

1 A PRIZE of $15 000 has been offered by Mr Edwin Gould for the most perfect and practicable heavier than air flying machine designed and demonstrated in this country and equipped with two or more complete power plants (separate motors and propellers) so connected that any power plant may be operated independently or that they may be used together.

CONDITIONS OF ENTRY

2 Competitors for the prize must file with the Contest Committee complete drawings and specifications of their machines in which the arrangement of the engines and propellers is clearly shown with the mechanism for throwing into or out of gear one or all of the engines and propellers. Such entry should be addressed to the Contest Committee of the Gould-Scientific American Prize 361 Broadway New York city. Each contestant in formally entering his machine must specify its type (monoplane biplane helicopter etc) give its principal dimensions the number and sizes of its motors and propellers, its horse power fuel-carrying capacity and the nature of its steering and controlling devices.

3 Entries must be received at the office of the Scientific American on or before June 1st 1911. Contests will take place July 4th, 1911 and following days. At least two machines must be entered in the contest or the prize will not be awarded.

CONTEST COMMITTEE

4 The committee will consist of a representative of the Scientific American, a representative of the Aero Club of America and the representative of some technical institute. This committee shall pass upon the practicability and efficiency of all the machines entered in competition, and they shall also act as judges in determining which machine has made the best flights and complied with the tests upon which the winning of the prize is conditional. The decision of this committee shall be final.

CONDITIONS OF THE TEST

5 Before making a flight each contestant or his agent must prove to the satisfaction of the Contest Committee that he is able to drive each engine and propeller independently of the other or others, and that he is able to couple up all engines and propellers and drive them in unison. No machine will be allowed to compete unless it can fulfill these requirements to the satisfaction of the Contest Committee. The prize shall not be awarded unless the competitor can demonstrate that he is able to drive his machine in a continuous flight over a designated course; and for a period of at least one hour he must run with one of his power plants disconnected; also he must drive his engines during said flight alternately and together. Recording tachometers attached to the motors can probably be used to prove such performance.

In the judging of the performances of the various machines, the questions of stability, ease of control, and safety will also be taken into consideration by the judges. The machine best fulfilling these conditions shall be awarded the prize.

6 All heavier than air machines of any type what ever—aeroplanes helicopters ornithopters etc—shall be entitled to compete for the prize but all machines carrying a balloon or gas containing envelope for purposes of support are excluded from the competition.

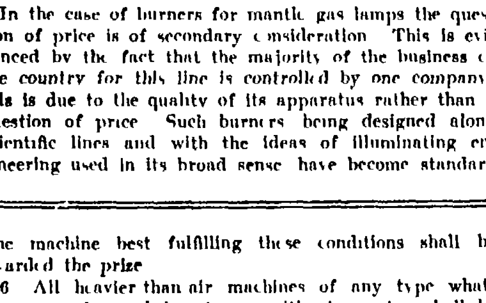
7 The flights will be made under reasonable conditions of weather. The judges will at their discretion order the flights to begin at any time they may see fit provided they consider the weather conditions sufficiently favorable.

8 No entry fee will be charged but the contestant must pay for the transportation of his machine to and from the field of trial.

9 The place of holding the trial shall be determined by the Contest Committee and the location of such place of trial shall be announced on or about June 1st 1911.

Sensitive Indicating Micrometer

The accompanying illustration shows a micrometer. The object of this tool is to avoid dependence on the sense of touch of the person handling the measuring tool. In the instrument shown the accuracy of the reading is independent of the sense of touch or experience of the operator, and a correct reading can be easily detected by the eye by means of an indicator. The principle of the device is simply this: The stationary member or anvil A is attached to a circular diaphragm B which is supported on its circumference in the head C. This head is cut away so as to form a cone shaped depression which, in connection with the diaphragm, forms a receptacle for mercury. The head C is provided with a stem, which fits into a bearing in the micrometer frame, and is slightly adjustable. A capillary tube D is partially imbedded in the frame, and has one end screwed to the stem of C by means of a collar E. An adjustable scale F is arranged at the center of the frame. When measuring the object to be measured will be pressed against the anvil A until the mercury in the tube reaches zero graduation on the scale F. For every piece measured the micrometer screw will be screwed down until the pressure on the anvil equals the standard pressure required for the mercury to indicate at zero on the scale. The tube of course must be made of glass so as to make the mercury column inside visible to the eye. It is evident that very close measurements can be obtained in this way. One objection to the instrument may be that it must be held in a vertical or nearly vertical position when in use. The principle involved however may possibly be used for other micrometer measuring instruments where the dependence on the sense of touch is objectionable.—*Machinery*



SENSITIVE INDICATING MICROMETER

Invisible Phosphorescence

ULTRA VIOLET phosphorescence first observed in fluor spar soon after the discovery of the Roentgen rays has since been detected in a great many substances. Pauli has recently discovered infra red phosphorescence in the sulphides of the alkaline earth metals. In Pauli's experiments the infra red as well as the ultra violet bands of phosphorescence were fixed by photography. A Lenard spark phosphoroscope was employed to produce phosphorescence in the substance which was placed in a quartz vessel before the slit of a spectroscopic camera. An exposure of 30 minutes usually sufficed for the ultra violet bands. The places of these bands in the spectrum were fixed by photographing the spark spectrum of zinc beneath the spectrum of the phosphorescent substance and the positions of maximum intensity were deduced from the sensitiveness of the plate for different wave lengths.

It was far more difficult to photograph the infra red bands owing to their extreme weakness and the small sensibility of the plate to infra red rays. The exposure usually continued ten hours, and often from thirty to fifty hours. The plates were sensitized with decyanine alone or mixed with cyanine. The positions of the maxima of the infra red bands were determined by photographing the line spectra of lithium and potassium and the continuous spectrum of a source of known distribution of energy according to wave length (the Hefner lamp) beneath the phosphorescent spectrum.

Phosphorescent bodies containing calcium sulphide show the most numerous ultra violet bands strontium compounds a smaller number and barium compounds none at all. These bands seldom extend beyond the wave-length 300$\mu\mu$ (millionths of a millimeter) and their position is independent of the method by which the phosphorescence is excited. Certain substances when very strongly excited by cathode rays emit momentarily radiations which extend very far in the ultra violet, to the wave lengths which are absorbed by the atmosphere.

Infra red phosphorescence is a much rarer phenomenon which Pauli has observed in only four substances. The phosphorescence exhibited by a fluoride of calcium and nickel extended farthest in the infra red region, to about 915$\mu\mu$. In all cases the infra red phosphorescence is very short lived, owing to the extinguishing effect of the infra red rays. The ultra violet phosphorescence is much more persistent.

Pauli's discoveries give support to Lenard's theory that the remarkable displacement toward the red which is produced in the bands of calcium strontium and barium sulphides by the addition of a heavy metal is due to electric oscillations in the atom of the last.—*La Nature*

feet) as indicated in the plan (Fig 2) the remainder of the pier 11 5 meters (37 7 feet) in length, being straight and served by a track of one meter (3.28 feet) gage, on which the locomotive and cranes are transported under the portal of the traveling crane.

The diagram, Fig 3, shows the arrangement of this electric crane as indicated in illustration Fig 1 designed to travel on a track, the rails being 5 meters (16 4 feet) apart and installed on the outer edges of the concrete structure The current is conveyed to the crane motors by three live rails or conductors as seen in Fig 1; the power being supplied to a sub-station on the pier structure and connected with an electric power transmission line supplying current from the mining generating station The crane has a capacity of 10 000 kilogrammes (22 046 pounds) when lifting a load with a radius of 12 n eters (39 4 feet)

The nethod of driving the concrete pile is shown in the front page illustration a portable steam boiler and hoist being provided on the scaffolding and a steam l ammer being utilized for driving the concrete pile. The ill stration Fig 5 shows the breaking of a reinforced concrete pile 19¾ inches square while under test and showing a remarkable resisting power and great strength These concrete piles were driven 3 3 meters (10 8 feet) apart as seen in drawing Fig 3 which shows the high water level as well as the lowest water level and the depth of the Gua lalquivir River adjacent to the rein forced concrete pile This concrete structure was designed and constru ted nder the directions of Juan Ma uel de Zafra an engineer of Madrid Spain and professor of Reinforced Concrete Construction" and of Harbors and Coast Lighting' at the engineering institu t n Esc ela Especial del C erpo

M Ph. Berger recently communicated to the Aca demie des Inscriptions a Jewish manuscript obtained by the Pelliot expedition, which is one of the most a ient we possess It is a prayer made up of passages taken from the Psalms or Prophets, written in good Hebrew characters of the square type with a still indimentary vowel notation. The leaf is folded upon itself and is intended to be carried by the owner Paris archæologists pronounce it to be of the eighth or ninth century A. D It has a great resemblance to the Hebro-Persian manuscript which M Stein brought from east Turkestan of about the same epoch. The manuscript has some noteworthy points which are now being studied.

Blue-Printing by Machinery

A Collection of Interesting Contrivances

By George J Jones

In the days before the general introduction of the blue-print, it was necessary to keep the plans and drawings of a structure or engineering project in an office or a shanty erected for the purpose The superintendents and workmen were obliged to familiarise themselves w th the plans as far as possible and whenever a doubt or question arose, it was necessary to interrupt the work wl ile an excursion was made to the place where the drawings could be consulted Under the old order of things a duplicate set of drawings represented such an outlay that it was not to be considered u less i nperatively de manded At present however beca se of the introduct on of the blue print almost every work nan can have a set of draw ngs at h s elbow In fact about machine shops a d similar establishments, t is the present cu tom to s pply copies of the original drawi gs to all workmen engaged on the job In this manner the work of con struction has been greatly facilitated

The blue-print was not long in working its way into popular favor However as these prints were exclusively made by the s n a spell of bad weather ser ously inter fere l with the work of turn ng out the pr nts thereby delayi g i nportant engineering or architectural projects d pendent on the delivery of the pr nts

Recently electricity has l een used for n aking these prints irrespective of weather conditions and there are ow several machines with which the printing is carried o almost a tomatically by artificial light.

One of these blue-pr nting machines which we illustrate herewith, not only does the printing but also washes and dries the prints running water being ut lised for the washing and the drying being done with gas or steam This machine is operated by a small electric motor It is designed to operate on an incandescent electric circuit supplying 110 or 220 volts direct urrent or 104 volt alternating current. It is said to be able to give 5,000 square feet of blue-printing per day Continuous prints can be made, of any length, with stop or readj istme t. The sensitised paper and tracing are fed in at one en l of the machine like a printing press and the print and tracing fall into a dark box at the other end The ten sion or pressure is automatic and does not depend on the operator, the contact being perfect.

The operation of the machine is exceedingly simple The roll of blue-print paper used passes with the tracing over the printer and is printed by a light from five electric arc lamps The tracing automatically drops off and the paper continues under the board into the wash ing trough and under the roller then passing upward A constant spray of water is throw over the surface of the paper at this point and runs o er the entire sur face The paper then passes between squeegee rollers to a roller at the top of the macl i e, thence it is stretched over a series of rollers and dried before being finally wound up on a roller provi led for that p rpose A gas or steam heater supplies sufficient heat to dry the paper perfectly Separate pr nts n ay also be washed an l lri l as easily as a continuo s length

The machine s supp l ed w th from three to five elect c lamps which are suspe ded in such a manner that the light from then falls directly upon tl e sensitised paper and tracing cloth as they pass The print is th s auto matically made without any nanipulat on on the pa t of the operator An electric motor moves tl e co t uou bands whicl carry the sensitised paper and tra ngs front of the lamp being on the san e circuit as tl e l p A double c ne speed cl nging me hanism is sed to change the speed

We also illustrate another machine which l nd j t l to take individual pri ts as they emerge from the pr nt ng machine an l put them through the finisl ing stages without any handling whatever It dispenses w th the slo nd splash wh ch resulted from the nanipulation of the prints by the old system The prints are washed l y a number of small streams of water directed upon the sensitised side of the paper only as the sheet hangs over a rod. Thus the paper is not saturated as it is in the bath, but the ferro-prussiate is just as thoroughly car- r e l off The sheet is left under these streams until the l sequent one is taken from the printing fra ne and en it is moved along automatically and the new sheet takes ts pl ce ut der the jets Tl e wasl ed print pro- g es es to a w p ng de ce whi h rn es the s rplus water fro he no stened s face S on tl e drying rod on wh h t was origin lly pla e l t s p a sed to a pa r of r ol g h ns wl l t k p l o l d ts l urd n an l rry it slowly pwar l th o gl a c rr t of warm air l h is it is passed over and b k an l fi lly finds its way to a rack in the rear of the mach e where the sheets hang separated from one another by a space of several inches, to permit thorough drying

An Appreciation of Thomas Davenport*

A Pioneer in Electrical Engineering

By T Commerford Martin

A NATION that spends as much every year for electricity as for daily bread may well entertain sentiments of reverence toward its pioneers in the electrical arts That part of our country which has given birth to some of the most notable of these pioneers may also well exhibit special pride in the fact and signalize it in appropriate manner It is indeed noteworthy that New England has to her credit a wonderful list of electrical worthies and through them has forever set deep and imperishable a stamp on American invention and industry as distinctive and unmistakable as the imprint of her poets in literature and her statesmen in politics No other geographic division blends these merits in equal degree with New England To Massachusetts as natives of Boston we owe Benjamin Franklin who snatched the lightning from the clouds and Morse who as father of the telegraph, made the lightnings talk To her also we owe Cyrus Field the great creator of submarine cables and his brilliant nephew the electric dynamo and railway pioneer, Stephen D Field both natives of Stockbridge From North Adams also came Frank Julian Sprague to whom more than any other living man is due our preeminence in the art and industry of electric traction on railroads and of electric elevators in buildings To the Wallace family of Ansonia Connecticut we are indebted for the development of our electrical wires and cables and for the production of our first lighting dynamos and arc lamps From Boscawen in New Hampshire came Moses Gerrish Farmer inventor and founder of the modern fire alarm system and original discoverer of the modern self exciting dynamo principle so fundamental in all our work And while neither Edison nor Bell was a native New Englander it was in Boston that Edison made and patented his first invention and in Boston that Bell gave to the world the telephone and the art of electrical speech transmission At Lynn for a quarter of a century also Elihu Thomson has been producing with lavish genius one beautiful invention after another in electric light power heat and measurement

Only yesterday, I received a letter from Randolph Vermont, from Mr A B Chandler President of the Postal Telegraph system informing me that he is a native of this state This veteran has been the successful organizer of the only competing telegraph system that ever survived in the United States while he and Charles A Tinker another Vermonter and one of the chiefs of the Western Union system were President Lincoln's confidential telegraphers at the White House during the whole Civil War There were four such men and it is singular to say the least that two of them should have been Green Mountain Boys

This is surely a noble record of illustrious names and rich achievements well distributed among sister states but my special duty and honor is to add thereto with emphasis in this region where he lived and dreamed and suffered and wrought the name of Thomas Davenport of Brandon Vermont the first American patentee and builder of the electric motor; the first man in all time to apply electric power to the operation of railways the first man in the world to hitch together those two tremendous forces electricity and the printing press Seen from the industrial standpoint it is significant that his patent if enforced to-day would embrace every one of the millions of electric motors now in service in the United States whose royalties would constitute an income equal to anything enjoyed by Rockefeller or Carnegie That we have escaped such a gigantic monopoly is something on which we and perhaps even the descendants of Davenport are to be congratulated but it would have been a merciful dispensation if the bitter bread of struggle and disaster eaten all the years of his short life by this extraordinary genius this prophetic village blacksmith could have been sweetened with the merest modicum of the vast wealth that his glowing conceptions have helped to create for the benefit of us all

Thomas Davenport was born at Williamstown Orange County Vermont a descendant in direct line of the Davenport family conspicuous in the early annals of the New Haven Colony He was eighth in a family of eleven, and it may not be an impertinence to suggest that neither New England nor Vermont is likely to breed more like him until it resumes the good old habit of such large families not merely to enjoy these fair hills and pastures but to go out and conquer the world at large Thomas was only ten when his father died only fourteen when he was apprenticed to the blacksmith trade A farmer's sons in those days had to depend for education on the little red school house To day perhaps a Vermont farm boy is lucky if he finds the little red school house in existence nearby All the formal education that Davenport got was for six weeks a year for a briefly indefinite number of years in a common district school house in a remote mountain town But he did get hold of some fragmentary portions of a scientific book, and as he blew the bellows so with it he fed and fanned the fires of his intellect Meantime he lived at Forestdale then a center for a little iron industry the blast furnace being located there doubtless because of the availability of charcoal He was a slender thoughtful lad and never appears to have been in very robust health. The whole drift of his thought is indicated by the fact that having made the acquaintance of another clever young fellow named Orange A Smalley wagon builder and wheel wright he formed the ambitious plan of going from place to place to deliver experimental scientific lectures The question of apparatus came up, and very naturally into the discussion came the wonderful "galvanic magnet" of Joseph Henry in operation at the Penfield Iron Works at Crown Point, only twenty miles away for sifting magnetic iron ore This magnet it was rumored would hold up a blacksmith's anvil, like Mahomet's Coffin between heaven and earth and Davenport determined to see it and get one During the intervening years the peripatetic lecture scheme seems to have been wholly abandoned a reason being found in his settlement at Brandon in 1823 as an independent working blacksmith and his marriage in 1827 to Emily Goss of that town, a beautiful girl of seventeen, granddaughter of the famous American traveler and explorer Jonathan Carver Under such stimulus he worked hard at his trade, prospered and built himself a brick house He was altogether in a fair way to accumulate a comfortable property for he was intelligent, sober upright, diligent but electro magnetism was his undoing We might almost call it malicious electro-magnetism" Going to the Penfield works in 1833 with $18 to buy iron for his business he spent the money there instead in part payment for an electro-magnet and batteries The iron was needed at the shop, but how much more he needed that magnet! We must even yet extend our retrospective sympathy to the Vermonters with wagons and buggies at his door then awaiting treatment. But shall we pity Davenport putting behind him material welfare for the sake of a wild fancy? As he handled the primitive little equipment "like a flash" he says 'the thought occurred to me that here was an available power which was within the reach of man" Yes it was there, and his was the superb divination of genius to detect it. He was like another Saul hunting down his father's asses and finding a kingdom Again I ask shall we pity him, or shall we not regard him as another of those who have come out of great tribulation to attain lofty ideals?—another of the immortals selected in some mysterious way to be the leaders of the race the fire bringers?

Certainly from the materialistic point of view that magnet was a curse like those legendary possessions inflicting injury upon their fatuous owners Never again was Davenport to know peace of mind Never again were his family to enjoy a home of comfort. Indeed they were called upon to share his sacrifices It was supposed in those days that wire needed silk for insulation His brave young wife took her silk wedding gown, cut it into narrow strips and with them were wound the coils of the second motor which in October, 1835 he showed in successful operation upon the judges bench in the courtroom at Troy New York Wifely devotion could hardly go much further We are told that when Palissy the famous French potter was close upon the discovery of his beautiful enamel he used up the furniture of his home and tore down the very woodwork lining the walls to feed the fires of his kiln Madame Palissy protested and remonstrated and it is not to be urged against her that she was unreasonable But while our respectful sympathy goes forth to Madame Palissy our admiring love is won by Mrs Davenport Later on Davenport learned that silk was not so essential but that cotton wound wire would do Thus the simple machinery used to cover the wire in our grandmothers poke bonnets and crinolines was equally serviceable in the electrical arts There has always been a close and curious relationship between electricity and the sex and it is largely through such work as that of Davenport that womankind are being emancipated from all manner of domestic toil All electrical apparatus is peculiarly susceptible to female manipulation, and it is not merely because it has to do with conversation that the telephone service is to day almost entirely carried on by women

Of course the inventor had friends in all his struggles though many of them including his shrewd and kindly father in law urged him to quit and settle down to the commonplaces of life Others like the talented Smalley worked with him awhile, and then drew off One of his strongest supporters was Ransom Cook, a furniture manufacturer of Saratoga Springs, who gave Davenport for some years the aid of his purse and the assistance of his unusual mechanical ability From Professor Turner of Middlebury College; from President Eaton of the Rensselaer Polytechnic Institute, from General Van Rensselaer, of Troy; from Professor Henry, of Princeton he received generous and substantial help, all of them appreciating that this shy untutored genius had made one of the greatest advances in physics and mechanics Everywhere he got good advice and compliments but such work required more than anything else the backing of real money Going sanguinely to Washington in 1835 to secure a patent on his first motor—he had already built about a dozen—he was obliged to return home penniless his errand unaccomplished, like Mark Twain's politician who drove to the National Capital in a four in hand to get his appointment and then after months of weary waiting slunk away on foot—without it. Time and again we find Davenport playing the part of a showman glad to pick up a few casual dollars in that way; but at no time getting out of financial difficulties or planting his feet firmly on the rock of commercial success. It must have been heart-breaking, and some of his letters show how the iron entered his soul. But his work never ceased, his interest never flagged, amid all vicissitudes He remained an inventor to the end of his brief life in 1851, only 49 years of age, in the retirement of an invalid on a small farm at Salisbury, Vermont. The very year of his death he was engaged on some beautiful and successful experiments directed to producing and sustaining the vibration of piano strings by electro-magnetism, being again a pioneer in the application of electricity to music. He was also engaged throughout his life in the invention and improvement of primary batteries, devising various types of plates and solutions.

And now for a brief glance at what Davenport actually did, a review of the reasons that warrant the erection of this memorial. There is always the danger of claiming too much for an inventor of the pioneer type; there is always the temptation to read into his record that which belongs only to later years when an art has been perfected by a multitude of men and by the courageous venturing of capital on perilous enterprises When Davenport came on the scene, Faraday and Henry had already done their great work; and the principles of both the electric generator and the electric motor had been clearly perceived and enunciated Yet there were no real motors before Davenport's time, and had the dynamo then been known his work would have been carried to instant fruition Davenport and others much later than he failed of the goal because they had no ready source of cheap current, and because the double function of the motor, its reversibility, so that if operated by exterior power it would generate current, was unknown It is at least twenty times as costly to use up zinc in a battery as to get the same equivalent electrical energy from coal driving a steam pipe connected to a dynamo In Davenport's day they had not learned to convert either the energy of steam or that of the waterfalls into electric current; and thus all the electrical arts lingered and languished, except telegraphy The reason is simple Beginning at the same time as Davenport and deriving it would seem, both suggestion and inspiration from his apparatus, Morse was able to make practical the art of communicating intelligence because it took such a small amount of energy to transmit signals by dots and dashes over a wire But when Davenport told the great Joseph Henry that he proposed to build his motors up to one horse power the cautious philosopher warned him to 'go slow" and hinted that electricity could not compete with steam In Europe, Jacobi like Davenport, as early as 1834, had obtained rotary motion from electro-magnets and in 1838 at the expense of Emperor Nicholas he propelled a boat on the Neva with his motor energized from batteries Here again the demonstration failed and ceased for lack of an economical source of current There is close rivalry as to dates between the physician in Russia and the blacksmith in Vermont, but both at least encountered the same fatal obstacle the lack of cheap current So far moreover electricity has made no triumphal entry into navigation but at a time when his native State had not a single mile of steam railroad Davenport built his little model of an electric road and asserted that that was the best way to do it Had he been able to harness up any one of the adjacent water powers, he could have proved the truth of his assertion That, however, was left for our day when electricity has demonstrated its superiority in every sense, for traction

In July 1834, Davenport had built his first motor with two stationary electro-magnets and two revolving, the changes of polarity in the two sets causing attraction and repulsion, with consequent rotation thus as he says, producing a constant revolution of the wheel' We have not advanced a bit since that hour nor can we, for as Davenport wrote at the time of securing his patent, the principle of his invention "was the production of rotary motion by repeated changes of magnetic poles." If anyone can improve on the method or the description of it he is entitled to a high place in history That patent, granted February 25, 1837, first of its kind in America, was broad as a Papal Bull, and embodied this claim "The discovery here claimed and desired to be secured by letters patent consists in applying magnetic and electro-magnetic power, as a moving principle for machinery in the manner above described or in any other substantially the same in principle." Writing of Davenport's work fifty years later, in 1891, Franklin L. Pope, the leading electrical patent expert and litterateur of his day, said: "If this patent which expired in February, 1851, were in force to-day, it is not too much to say that upon a fair judicial construction of its claim, every successful electric motor now running would be embraced within its scope."

The crude motor of 1834 was soon followed by an improved form in 1835 and by many others as the years went by The motor of 1835 is interesting as being the earliest known instance of the application of the modern commutator An elastic contact-spring or brush pressed against metallic segments fixed upon a revolving shaft, so that the shifting polarity of the magnets was maintained as current was received from the battery In 1834 and 1837 motors and models were built illustrative of electric railway work, and the motor was shown to the public running on a miniature circular track 24 inches in diameter The battery was not carried by the car but was placed on a tray at the center of the circle and contact was made through mercury cups. This device embodied therefore, remotely but inevitably, the idea

* Issued by the Vermont Electrical Association

of a central station source of supply Later inventors still carried their batteries on the car, just as a storage battery car does to-day Moreover the motor field magnets and those of the armature were connected in parallel, so that at that early date we have a shunt wound motor, each core being wound twice with 24 revolutions of No. 10 wire connected in parallel. Another striking fact was that as the model itself showed, the circular track was used as the return circuit, just as every trolley car uses it to-day In 1836 his motor model filed at the Patent Office in Washington was destroyed by fire, as well as 7,000 other models; just as another Davenport motor at the Rensselaer Institute Troy was destroyed in 1862 by fire This kind of fatality pursued much of his work In 1893, the present speaker exhibited at the Chicago Columbian Exposition one of these Davenport railways, where it received an award Its exhibit was requested for the American section of the Paris Exhibition of 1900, and it was shipped early in that year with the Government exhibits on the steamer "Pauillac" Violent storms swept the Atlantic and the steamer has never been seen since In like manner disappeared the first dynamo ever placed on a ship Mr Edison equipped the Arctic exploring ship Jeannette" with a little dynamo arranged so that if necessary it could be driven by manual power "to help keep the men warm" The ill fated "Jeannette' like the 'Pauillac" now lies in ocean depths awaiting some cataclysm thousands of years hence, when men may see again these relics of their remote ancestors preserved in the museum of Eternity

Nothing daunted by fire Davenport made a third trip to Washington in 1837 and secured his memorable patent first of a long line in which the inventive genius of our people has shone forth so strikingly During the same year, Davenport and his friend Cook established themselves in New York with a laboratory and shop and gave exhibitions of their apparatus to crowds of visitors, including Morse, already busy on his telegraph and Page who 14 years later operated a battery-driven locomotive of 12 horse power on the Washington and Baltimore Railroad. In March, 1837, the partners, to raise funds for their work, organized the Electro-Magnetic Association with its stock divided into shares So far as can be ascertained this was the first electric stock company in America, first of several thousands now representing a total capitalization of ten billions of dollars in bonds and stock and earning gross over $1,200 000,000 annually The manager of the financial transactions of the partners was not, however particularly honest, and it required a chancery suit to secure an accounting, as he turned in only $1 700 out of the $12,000 received This disgusted Cook and led to his withdrawal from the enterprise As a piece of misfortune the incident was matched later about 1840 when a gentleman in Ohio proposed to join Davenport and gave him $3 000 in Ohio bank notes for an interest Davenport had spent just $10 when he learned that the bank had just broken, and that the money had become worth nothing

Davenport was not only the first man to drive a printing press by electric motor but he was the editor and publisher of the first electrical journal in the world In 1839 he gives details with regard to the operation of a rotary printing press with a motor weighing less than 100 pounds In January 1840 he began in New York City the publication of a journal which he called *The Electro Magnet and Mechanical Intelligencer* which was not only devoted to electricity but was printed by electrical energy There is evidence that a second number was issued, but it is doubtful if the periodical ran to a third number for on January 28 he wrote to his brother in Brandon about the difficulties inflicted on him by impecuniosity He had done all the editorial work himself and found that it would cost $10 per week to secure editorial articles There was no advertising and I have no way to get a few dollars except by the prospect of getting subscribers" The paper seems to have gone prematurely to its death but only a few months later on July 4th Davenport came out with another journal which he called *The Magnet* This had a real live editor salary unknown but it does not appear to have had any longer life than its predecessors Both were tiny little quarto sheets, but they were the first of their kind in America, probably first in the world and made Davenport the father of electrical journalism. Copies of both journals are preserved in the offices of the National Electric Light Association As an electrical editor of thirty years standing the speaker is proud to greet the village blacksmith as a fellow craftsman and proud again to assist in this tribute to the first of his profession in America It is interesting to note that Davenport also employed various motors to drive his printing press of the solenoid type or "axial magnet" in which reciprocating motion was obtained by the attraction and repulsion of a core within a hollow electromagnet While the principle was not altogether new with Davenport his caveat filed in 1838 with the United States Patent Office is believed to be the earliest proposal to employ the principle for industrial purposes

These are the bare outlines of a fascinating record on which one would love to linger It must be added however as an item of interest that it was proposed to develop Davenport's invention in England and that he actually took out an English patent This may or may not have been the first American invention or Yankee notion patented abroad but it was beyond any doubt the first electrical one again first of a long series It is really extraordinary how many things Davenport was the first American to do They may not have been done on the grand scale but it is not magnitude that counts What does count however crude is the conception the idea the execution of the idea in practice In all this we shall find Davenport's record astounding and unimpeachable

These then are in brief the reasons why we electricians honor Davenport and revere his memory These are the reasons why his native state and his country should be proud of him These are the reasons why struggling against adversity dying in poverty and long obscured by forgetfulness this modest simple son of Vermont stands forth as conspicuous as one of her granite mountains among the immortals who for the benefit of their fellowmen have tamed and utilized the lightnings

Magnetic Alloys

A New and Important Field of Investigation

By H A Knowlton, University of Utah

WITH respect to their magnetic properties all materials can be divided into three classes:

(1) Diamagnetic substances, such as bismuth, which, in a magnetic field set themselves with the long axis of the specimen across the lines of force and tend to move from the stronger to the weaker part of the field

(2) Weakly para magnetic substances, such as many metallic compounds and their aqueous solutions which are drawn into the strongest part of the field but do not exhibit phenomena by hysteresis or magnetic saturation

(3) Strongly para magnetic or ferro magnetic substances such as iron including those usually spoken of as magnetic which are drawn with a considerable force toward the strongest part of the magnetic field and are further distinguished from the weakly para magnetic substances by the phenomena of magnetic saturation

Besides iron the latter class includes magnetite (Fe_3O_4), pyrrhotine (Fe_7S_8), nickel, cobalt and a number of alloys some of which contain one or more of the ferro-magnetic metals, while others are composed wholly of metals which are non magnetic when pure, *i e* either diamagnetic like copper or weakly para-magnetic like manganese.

The most important example of this latter class is the so-called Heusler alloy, discovered in 1903, which consists of copper manganese and aluminium The composition by weight of a typical example may be taken as copper 65 per cent, manganese 23 per cent aluminum 12 per cent, although equally good quality may be found in samples which differ considerably in composition In any case, the manganese and aluminium should be present in approximately atomic proportions, as if more than about 25 per cent of manganese be used the alloy becomes so hard as to be unworkable The magnetic properties appear to be inherent in certain crystalline masses, not themselves the magnetic units but which contain as one of their structural elements, molecular groups that are magnetic at proper temperatures

The magnetic quality of any particular specimen depends much more upon its thermal history than upon its composition, although the maximum attainable intensity of magnetisation—*i e* the saturation value after most favorable heat treatment—depends upon the composition As is well known, iron loses its magnetic properties when heated to 785 deg C and regains them upon being cooled to a slightly lower temperature The Heusler alloys undergo a similar transformation at temperatures which range downward from 300 deg C to 0 deg C. or even lower, according to their composition When cooled below their transformation temperature in some cases the alloys are found to be nearly or quite non magnetic while in other cases their magnetic quality is greatly improved after passing through a thermal cycle These contradictory results have been shown to depend upon the manner of cooling In general, the transformation from the magnetic to the non-magnetic state takes place over a range of about 50 deg C. The effect of annealing at or just above the upper limit and subsequently cooling at a fairly rapid rate is generally favorable, while annealing at or just above the lower limit is exceedingly injurious. The effect of passing the alloy through several such heat cycles is shown by the curves in the diagram in each case the specimen was kept at the temperature indicated during several hours and then allowed to cool in air If quenched from a temperature 50 deg to 100 deg above the upper limit the specimens were non magnetic

As noted the transformation temperature of the alloys appears to depend on the percentage of copper present

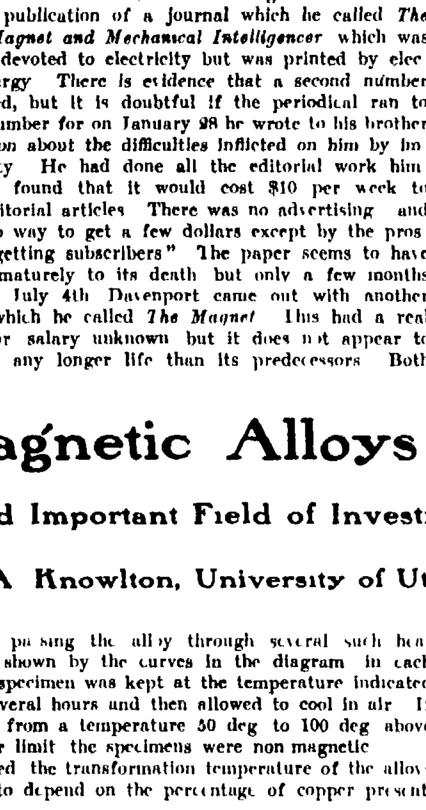

DIAGRAM SHOWING EXPLANATION OF CURVES ALL CURVES REFER TO THE SAME SAMPLE

20 6 per cent. Mn 8 2 per cent. Al 0 2 per cent Cu 0 2 per cent. Si Curve 1 best conditions after heating to 1 deg during thirteen hours 2 after eight hours near 200 deg and five hours between 275 deg and 300 deg (an other heating of five hours at 100 deg and two hours at 200 deg produced no further change) 3 five hours at 200 deg 225 deg 4 annealed at 225 deg after heating above transformation point 5 after nine and a half hours at 250 deg 6 after fourteen hours at 200 deg 350 deg

One specimen containing about 70 per cent of copper, can be picked up from a cake of ice by a small magnet but cannot be picked up from a table in a room at ordinary temperatures, as the upper limit of its transformation range is about 20 deg C. and its full magnetic quality is not attained above about 15 deg C below zero This specimen when tested at 0 deg shows a rather low magnetic permeability, becoming saturated at low values of the field; it exhibits almost no hysteresis loss, all of which phenomena are characteristic of all specimens near their upper transformation limit

Microscopic examination of a considerable number of specimens has shown that extensive changes in the crystalline structure always accompanies the changes in magnetic quality

No sample in which the bright crystals were lacking was at all magnetic under any conditions, while all specimens showing these crystals were magnetic at temperatures below the transformation temperature Apparently the magnetic quality depends upon some constituent of the bright crystals which may take on or lose its magnetic quality without the crystalline mass being destroyed the transformation involves very slight energy changes as careful observation has failed to afford any definite evidence of recalescence within the transformation range

The alloys in which aluminium is displaced by some other trivalent metal have been less studied but appear to behave in a way quite like the above Besides these, an alloy of a small amount of iron with larger amounts of nickel and chromium is strongly magnetic while curiously enough an alloy containing 25 per cent nickel and 75 per cent iron is non magnetic unless cooled to a temperature somewhat below 0 deg when it becomes magnetic and remains so until strongly heated, consequently a bar of nickel steel may be cut in two parts and after proper treatment under apparently the same conditions the one piece may be in the magnetic and the other in the non magnetic condition

Within the last few years alloys of iron with about 4 per cent of silicon have been found to be of great value for commercial use in building transformers as the hysteresis loss may be considerably less when the transformer core is made of such alloyed steel than when soft iron is used

From what has been said it is evident that the study of the magnetic properties of alloys is of great importance both because it seems likely to help us toward a better understanding of the nature of magnetism and because of the technical improvements which may result It should perhaps be stated that none of the alloys except those containing large amounts of iron are valuable in commercial work

In conclusion it is interesting to notice that Mr O C Clifford has found alloys of copper and tin more strongly diamagnetic than copper itself thus duplicating the phenomena of the Heusler alloys among diamagnetic materials—*Science Progress*

The Power Plant of Lesquinn

AN extensive steam and electric plant is erected at Lesquinn France where the Thomson Houston Company has shops for manufacturing Curtis steam turbines, in connection with the Paris central works All the machine tools are run by electric motors The boilers are needed for use in the electric plant as well as for testing the turbines and an extensive testing room is fitted out The boilers have a large output, 40 000 pounds of steam per hour and the super heaters give various temperatures of steam for testing purposes A forced draft is given by the use of properly combined motor-driven blast fans and smoke flues Four boilers are used built in two pairs and each pair is operated by a 30 horse power motor blower Anzin briquettes and also coal are used in the grates The condensing plant uses two condensers with the necessary pumps and scarcity of water required the use of an extensive water-cooling plant

New Methods in Astronomy*

Their Application to the Evolution of Our System

By F W Henkel, B A., F R A S

During the last few years the researches of eminent British and Continental astronomers have thrown a flood of light upon some of the most recondite problems of the science Among these may be especially mentioned the work of Dr Hill M Poincaré and Sir George Darwin, and we propose giving a simple account of some of their results as well as the bearing these have upon theories as to the origin of our system The Laplacian nebular hypothesis greatly shaken by later discoveries and the critical investigation of its postulates seems likely to undergo the fate prophesied for it by the late Mr Proctor founder of *Knowledge* and his words may be quoted here "If ever proper inquiry is made into Laplace's nebular hypothesis, that also will be still more decisively rejected" (*Old and New Astronomy* p 638) We shall have occasion to allude to some of the alternative hypotheses an account of part of Prof See's work has already appeared in *Knowledge*

Newton in his immortal Principia has once for all solved the problem of two bodies "Given two spherical masses acting on one another according to the law of gravitation and their position and motions at any time, to find their motions at any future or past time" The planets move in ellipses closely approximating to circles round the sun the comets mostly move in parabolas, a few in very elongated ellipses and perhaps a very few in hyperbolas round the same center of force This however is only an approximation though very close to their motion arising from the fact that the mass of the sun is so enormously great compared with that of any of the planets that the attraction between sun and planet is the main factor in determining the path of any one of these bodies Every planet moves in an orbit round the sun which is very nearly the same as it would be were no other bodies but itself and the sun to exist; the small deviations between the actual motion and this ideal motion are known as perturbations and are due to the disturbing action of the other members of the solar system arising from the difference of their attractions upon the sun and the planet in question in each case Owing to the fact that, as we have mentioned above all the planets are much smaller than the sun we may by a series of approximations determine these perturbations one after another and add their results till we obtain a satisfactory agreement between theory and observation The general problem of three bodies is however far beyond the capacity of our present mathematics to solve and all that can be done is to take some simple cases and then consider others approximating to them as nearly as possible

The moon moves in a path around the earth which is not very different from a circle but owing to the disturbing action of the sun the form of this path is continually undergoing slight variation In this case though the disturbing body is not small yet on account of its much greater distance the sun's disturbing force or its difference of action upon earth and moon is only a small fraction of the earth's attraction upon the moon Were the sun to attract earth and moon equally and along parallel directions there would be no disturbance of their relative motion In a similar way we may say that any

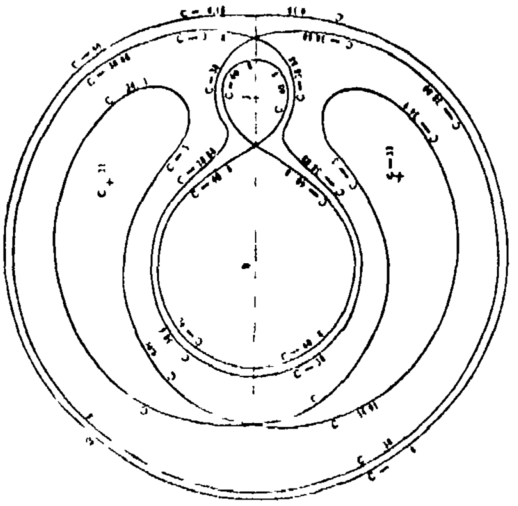

Fig 1 Curves of Zero Velocity (After Darwin) Critical Values Only Shown

external force acting equally upon all members of our system will produce no change in the planetary and satellite orbits Whatever force may be moving our sun along its mighty path toward "Hercules" (or Vega), is equally drawing its family of planets satellites, comets and meteors Even as it is however, with the comparative simplification introduced by the smallness of the disturbing force the "Lunar Theory" is one of the most complex branches of applied mathematics, and though the general agreement between the results of theory and observation affords one of the most complete verifications of the exact truth of Newton's law of gravitation there are questions even yet awaiting solution Dr Hill, in 1876, pointed out a new method of treating the problems of the lunar motion, and he took as the first approximation, not the ellipse, but what he called the variational curve as the moon's orbit. The moon is considered to move in a circle distorted by the sun's attraction, and this orbit is called a "periodic one," its period being one synodic month (i. e., interval from new moon to new moon or full moon to full moon, 29½ days) The eccentric form and the change of inclination (the moon's path is not in the plane of the earth's orbit but is inclined at an angle of about five degrees to it) are "free" oscillations about the periodic orbit, the "annual equation" (arising from the varying distance of the sun at different times of the year) is a "forced" oscillation M Poincaré, M Gyldén, and Dr Charlier have continued this

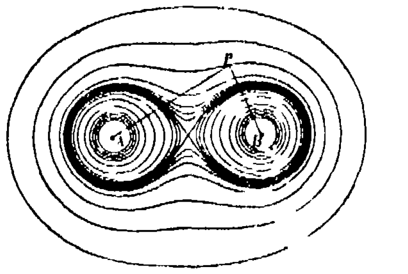

Fig 2 Equipotential Surfaces About a Double Star With Equal Components of Equal Mass (After Darwin)

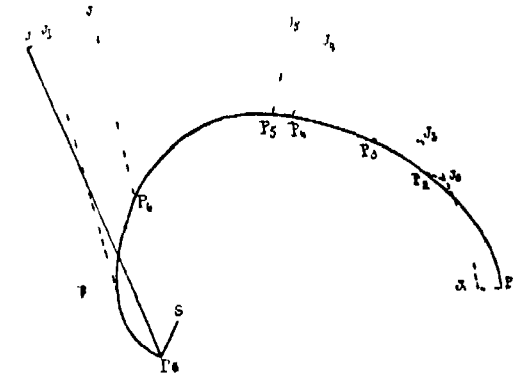
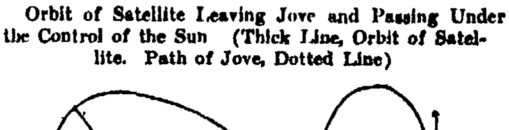
subject from the purely mathematical point of view, while Sir George Darwin has also dealt with it numerically in a comparatively simple manner, and we propose to give a brief account of some of his work He begins by considering the case of three bodies, called respectively the sun a planet moving around it which he calls Jove, and a third body whose mass is infinitesimal (so that it will produce no appreciable effect upon the motions of the other two) which he calls the planet, or satellite Jove (J), of unit mass, moves round the sun, of mass* ten in a circle, and all three bodies lie in one and the same plane He first obtains what is called the equation of relative energy (the well known Jacobian integral $V^2 = 2\,\Omega - C$) Since for real motion V^2 must be positive $2\,\Omega$ must be greater than or at least equal to C and so the planet can never cross the curve represented by $2\,\Omega = C$ which agrees with Dr Hill's result in assigning definite limits to the past and future position of the moon in our system He then considers the form of the curves obtained by giving different values to the constant C called the constant of relative energy For large values of C they are closed ovals around S and J respectively with an outer branch around both S and J The larger oval shrinking as C become less, unites with the inner oval around J and the curve becomes of horseshoe shape The horse shoe then narrows at the middle and breaks into two elongated portions, these gradually shrinking into two points equidistant from S and J Fig 1 shows the form of the curves for the critical values †

It was shown by Lagrange, more than a hundred years ago that there is an exact solution of the problem of three bodies when they are each at one angle of an equilateral triangle which revolves uniformly, and since two triangles of equal altitude may be drawn on the same base (one above and the other below SJ) there are two such positions This is approximately realised in our system A minor planet recently discovered revolves at about the distance of Jupiter from the sun, and this arrangement appears to be a stable one In addition to the above determinations, Sir George Darwin has also considered the case of a satellite leaving Jove and passing under the control of the sun, and Fig 3 shows the path for $C = 39$ referred both to axes fixed in space and to revolving axes. The full curve shows the path of the planet the dotted one is that of Jove, and lines are drawn joining the simultaneous positions of these bodies (In order not to complicate the figure only a few of these are drawn) The body here makes a single revolution around Jove and is then drawn off to the sun, but it may happen that several revolutions around the former would be made until conjunction takes place at "apojove" (greatest distance of planet and Jove), and then it will revert to the sun again "It seems likely that a body of this kind would in course of time find itself in every part of the space in which its motion is confined" (Darwin) Thus it would at last collide either with the sun or Jove, and it has been suggested by the same writer that in this way stray bodies are gradually swept up by sun and planets Some non periodic orbits passing from Jove to the sun are drawn in Fig 4, and it will be seen that one of these paths has a sharp cusp (lying on the curve of zero velocity) another is looped, and so on

Regions within which stable orbits are possible and others for which they cannot exist, are found, and in this connection we may later find an explanation of Bode's law as to the distances of the planet and satellites from their primaries. In his later work, Sir George Darwin has considered possible retrograde orbits, all his former researches having been on orbits where the motion is direct, i. e., the same direction as that of all the planets and most of the satellites, and has traced the forms of paths of bodies ejected from sun toward Jove and *vice versa*. Modes of transition between direct and retrograde orbits are also considered, passage through the apices of the equilateral triangle on SJ as base already mentioned being suggested as one method. From a consideration of the figures given we may gain much information as to the kind of orbits possible, and the limit of distance between planets and satellites. For values of C greater than 40 18 the third body must be either a superior planet moving outside the larger curve, or an inferior planet moving inside the larger internal oval, or a satellite inside the smaller oval, and it can never change from one of these forms to either of the others, "so that this limiting value gives superior limits to the radii vectores of inferior planets and of satellites which cannot sever their connection with their primaries." When C is less than 40 18, and greater than 38.88, the third body may be a superior planet, or an inferior planet, or satellite, or a body moving in an orbit partaking of the two latter characteristics, but it cannot exchange from the first *rôle* into either of the others When C is less than 38.88, and more than 34 91, the body may move anywhere except inside of the "horse-shoe" shaped space Here the distinction between planetary and satellite motion does not exist, and the body may change from any one of these modes into any other When C lies between 34 91 and 33, the only regions where motion is not possible are within the leaf-like folds on each side of the line SJ, and these diminish to the pair of points marked with crosses (Fig 1), for the value $C = 33$. Lastly, when C is less than 33 the body may move anywhere. As a general result it is concluded that unstable orbits are such as to lead to the ultimate absorption of bodies moving in them into one or other of the larger bodies, and though the problem in our planetary system is much more complicated from the large number of planetary bodies, yet, as we have seen, several interesting features have indicated explanations We have now to briefly notice the bearing of these results upon cosmogonic theory, and some modifications suggested by Prof See By supposing the existence of a resisting medium universally diffused throughout our system, of whose presence we have some evidence, we get the well-known result that when a body revolves about the sun or a planet, the resisting medium at every point decreases the velocity, and thus gives the central attraction more effect, the revolving body being gradually drawn nearer to the center of force For Encke's comet this change seems more rapid than for any other known member of our system. For orbits differing from circles the result of the action is also to diminish the eccentricity or make them more nearly circular This was well known to Laplace, and the proof is given in works on analytical dynamics. Thus a particle moving within one of the inner closed surfaces,



A Orbit of Satellite Leaving Jove and Passing Under the Control of the Sun (Thick Line, Orbit of Satellite. Path of Jove, Dotted Line)



B Referred to Moving Axes

Fig 3.—(After Darwin)

of which we may regard the curves (shown in Fig 1) to be the traces on the plane of paper, will gradually draw nearer its center, and, its speed increasing, its periodic time will be diminished; for a body moving within the "hour glass" shaped space or the pear-shaped region surrounding both bodies (Fig. 1) will drop nearer and nearer to one or other of the masses, and may finally pass within the closed surface and acquire a constant of relative energy such that it can never escape again from that region. The moon is now within such a closed surface about the earth, and cannot escape therefrom, and it has been accordingly supposed that it has not at any time been outside; but if we admit the action of the resisting medium there is a possibility of our moon's

* Reprinted from *Knowledge*.

*The value of ten for the mass of the Sun in terms of Jove is taken for the purpose of exaggerating all the phenomena of perturbation as compared with those in our system, so as to give a clearer view of their nature.

†We may regard these curves as the traces on the plane of the paper of surfaces of zero velocity By taking all three bodies in one plane the problem is reduced to a two dimensional one.

having been an independent planet which approached too nearly to the earth and became captured At present most astronomers give in their adhesion to Sir George Darwin's theory of tidal evolution, according to which our moon once formed part of the earth's substance. It is supposed that once upon a time the latter was rotating much more quickly than at present, and that a portion separated from the rest and became the moon. The time of the earth's rotation was estimated to be then about two and a half hours, so that the "centrifugal force" caused its rupture. The separated portion may have gradually receded to its present position by tidal action Difficulties as to the possibilities of the moon's holding together under tidal strain when so much closer to the earth than at present, and the cause of the supposed very rapid rotation of the earth in early ages, have been raised by various writers, so that we may at least regard the alternative capture theory and action of the resisting medium as a possible explanation, though it seems difficult to imagine that all the relations pointed out by Sir George Darwin are purely accidental. The Laplacian hypothesis, with the modifications suggested by Faye and others and supplemented by the theory of tidal evolution, has been nevertheless shown to be untenable, and the evolution of the planets by separation of rings of matter from the central condensation as it contracted must be definitely abandoned. Briefly stated the theory is as follows: The matter now forming sun, earth and other planets was at one time in the form of a hot gas and was of approximately spherical form. It rotated slowly on its axis, the rotation increasing in swiftness as it grew colder and contracted In time rings of matter were left behind Each of these rings gradually collected into a single globe, and thus the planets came into existence A planet thus formed continuing to revolve itself in turn abandoned rings in contracting and thus arose the satellites. This process is illustrated by a well-known experiment, devised by Plateau He formed a mixture of alcohol and water of the same density as oil (water being heavier, alcohol lighter) and poured into this mixture a quantity of oil The oil sank about halfway and floated in the middle of the mixture as a round ball. By means of a disk attached to a wire Plateau made it rotate The rotation caused the ball to spread out into the form of a spheroid; then, as the speed increased, a ring was thrown off which revolved around it The ring broke up after a time and collected into a smaller globe which rotated and also revolved around the larger, then another ring was thrown off as the speed again increased, and so on Babinet, however, in 1861 showed that the original nebula imagined by Laplace could not have rotated with sufficient speed to detach any of the planetary masses, and his argument has been extended by Prof See to show that, similarly the satellites could not have separated from their primaries. There has therefore been proposed an alternative fission theory that secondary condensation nuclei might be formed by gravitational instability within the gaseous nebula, as also the capture theory referred to above together with the "spiral" nebula form A spiral nebula is supposed to be formed from a sun by the near passage of another star the consequent ejection of matter forming two spiral arms bearing nuclei at irregular intervals The particles of these arms move around the central nucleus in elliptic orbits, the planets being formed by the gradual growth of these nuclei, by the addition of small "planetesimals Prof See considers that our solar system was formed from a spiral nebula and that the planets have not been detached from the central mass by rotation, but "captured," or added on, from the outer parts of the nebula their orbits have been "rounded off" by the resisting action of the medium in which they move and the particles moving in orbits confined to regions of the nature of those indicated in the researches of Darwin alluded to in the earlier part of the paper Moving against resistance they will all drop nearer to one or other centre of attraction some will become satellites of one planet some of another while yet others will collide with and be absorbed by these latter or fall upon the sun Thus the greater masses will increase, and in some such manner the "secular acceleration" of the sun and the unexplained acceleration of Mercury may be explained In our system we have a large central mass, the sun with attendant planets, but in some cases we may have a more nearly equal division of the matter, as in the double stars Fig 2 shows the equipotential surfaces about a double star with equal components (or rather their traces on the plane of the paper) In such cases the planets which are developed if they can continue revolving in stable orbits, will have to be near either one or other of the large masses, or else at great distances from both, if their motion is to be of a permanent character However, the existence of such bodies, though probable is not likely to be revealed by any increase in telescopic power of our present instruments. Great numbers of spiral nebulæ are now known to exist, scattered all over the heavens, while there are very few of the oblate spheroidal form, such as the hypothesis of Laplace assumed to be met with in the sky This was pointed out by Proctor and Ranyard (*Old and New Astronomy* § 1445) Such nebulæ as we see have a greater analogy with the solar corona than with the fiery condensing mist conceived of by Laplace The opposite branches often seen on photographs of spiral nebulæ are considered to represent the "original streams of cosmical dust coiling up and forming spiral systems." If the streams converge and the mass becomes very dense at the center, a double star may be formed.

The theory of the action of a resisting medium gives results exactly the opposite of tidal friction. The latter usually increases the major axis and eccentricity of a planetary orbit; the resisting medium decreases both these elements. "In the actual universe both causes are at work, sometimes one predominating, sometimes the other"

In the growth and development of our system all these various agencies may have been called into play, so true is it that here, as elsewhere, no single explanation is self comprehensive and exclusive of other hypotheses The mind of man is so constituted that it cannot help speculating on such topics, but it is well to remember that all our knowledge, both of time and space, is essentially relative and conditioned; no absolutely undisputed truth is admitted by all philosophers alike so that in some

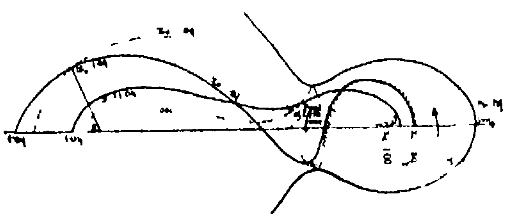


Fig 4—Non periodic Orbits Passing from Jove to the Sun (After Darwin) Outer Thick Line Curve of Velocity C = 39 0

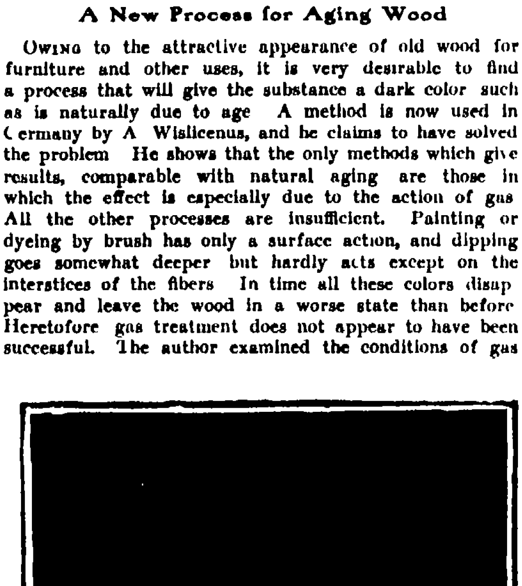
respects we seem less advanced than was thought to be the case a century ago The sun was supposed to have an absolute velocity of about fifteen miles per second "toward a point in the constellation of Hercules, but as has been pointed out, this result has been overthrown by the work of Kapteyn Numerous optical and electrical experiments have been made at different times with the view of determining the absolute velocity of the earth, but such effects have always failed to appear

The vast masses of observational data accumulated by the persevering industry of self-denying men of science,' together with the mathematical researches we have outlined above, are leading to more accurate views than any that have been held hitherto and the results already obtained should give us encouragement in our efforts to trace the process of Creation but we must more than ever feel how little after all is yet known compared with what remains to be learned

A New Process for Aging Wood

OWING to the attractive appearance of old wood for furniture and other uses, it is very desirable to find a process that will give the substance a dark color such as is naturally due to age A method is now used in Germany by A Wislicenus, and he claims to have solved the problem He shows that the only methods which give results, comparable with natural aging are those in which the effect is especially due to the action of gas All the other processes are insufficient. Painting or dyeing by brush has only a surface action, and dipping goes somewhat deeper but hardly acts except on the interstices of the fibers In time all these colors disappear and leave the wood in a worse state than before Heretofore gas treatment does not appear to have been successful. The author examined the conditions of gas



The Spiral Nebula M 51 Canum Venaticorum (After See) Illustrating the Spiral Theory

action and finds that it is essentially the same as that which occurs in natural aging of wood, so that he may deduce an artificial process which gives about the same results as the natural one The new process is in use at an establishment at Dresden and it is rapid and certain, as well as cheap Wood tissue contains about 50 per cent cellulose, also lignine and imbedded mineral and organic matter, among which are tannins and iron salts. It is difficult to find which of these latter constituents is accountable for the brown color of old wood. We know that lignine becomes yellow and even brown by exposing it to air and light Book and journal paper owe their yellow color to it This paper is, in fact, a mixture of cellulose (often known as chemical paper paste), free from lignine and extracted from wood by what is known as the bisulphite process, and of soft wood paste still containing all the constituents of wood tissue and therefore the lignine On the other hand it appears that tannins and iron salts contained in the sap which are very sensitive to oxygen and light, also play a part, for woods having much tannin become brown more rapidly than others in general. However this may be, the finest natural coloration of wood is seen on Alpine chalets placed at very high altitude near the snow line where the air is pure and the light is rich in ultra violet rays The color may even reach a blackish brown for wood several centuries old But even in these conditions we observe old wood which is quite discolored and becomes a snow white This is produced near stables etc, and it is due to ammonical vapors added to other agents, such as water vapor oxygen and ultra violet rays Analysis shows that such wood is entirely composed of cellulose and the lignine and all imbedded matter is eliminated or destroyed by the combined action. In the case of browning, as well as of bleaching the action is a deep one. Combining the effect of these four agents in different proportions it was possible to obtain tints varying from gray to browns The old empirical methods for artificial aging were based upon this Wood was buried in trenches under a mixture of muc and more or less complex manures giving rise to a fermentation and thus ammonia was slowly given off However the brown color was due more to impregnation of colored liquids and a commencement of rotting, and the darkest color rather resembled water soaked wood than that which is exposed to the air of the mountains.

In the new process, the wood is placed horizontally in 2 foot ditches having a porous bottom and covered with a mixture of earth containing some humus but which should not be clay or sand exclusively A grain of 3-7 millimeter (0 12-0 28 inch) size should be obtained by sifting so as to be very regular Should such earth not be had common ashes can be used instead as these have always enough carbon for the purpose The ashes are crushed and sifted Such material is always permeable to water and air and does not hold back any great amount of liquid when the trench is watered or rained upon Alternate watering and draining set up a great circulation of air which gives an oxydizing action The slow oxydizing of the combustible materials of this layer no doubt gives rise to hydroxyl which has a strong effect on the wood Such an effect is increased or completed by the addition of substances which give off ammonia slowly Numerous tests show that the best results are obtained by adding 2 per cent of a mixture of ammonia salt and quicklime to the earth We mix them by a spade upon a plank floor using earth as dry as possible so as to avoid loss of ammonia For the same reason quicklime is to be employed For the best effect however, we use powdered chalk and sal ammoniac such as is sold for fertilizer Under the action of moisture a small amount of sulphate of ammonia which is dissolved out, comes in contact with the carbonate of lime There is formed sulphate of lime and carbonate of ammonia, and the latter is easily decomposed to carbon dioxide gas and ammonia so that the latter gas is given off slowly and regularly thus being more efficacious than if we used quicklime Better results are had by giving a good drainage and covering over with fine sand or cloth sacks so as to keep in the ammonia Thus treated the wood becomes colored in the whole of its mass, and the process can be used for any kind of wood But some woods give better results than others Oak is one of the best and is rapidly colored to a fine brown This goes down very deep below the surface of the wood Ash and beech wood can also be used very well Resinous wood such as pine is not so good However the process can be applied to redwood cypress and pitchpine

A Sliding Gate Dam

THE new 30 000 horse power Tuilere hydraulic plant in France is remarkable from the fact that it uses a slide gate barrage and there are but few examples of this construction for large plants in Europe Another lies on the Rhone near Geneva The Tuilere station ranks among the large European plants of to-day As to the barrage, it is composed of eight spans containing the same number of metallic gates Piers are built at a height of 165 feet above the water stage and between these the gates work in a slide Over the tops of the piers is a continuous metallic flooring structure and it carries the electric motor driven winches which raise and lower the gates by chain and counterweight The fore ends of the piers which contain the grooved sliding way are of reinforced concrete strengthened by vertical I beams which go down in the foundation bed The width of the gates is 36 feet and the height is 44 feet In this plant the turbine house lies alongside the dam so that the water comes almost direct to the turbine chambers A head of water of 20 to 40 feet is here used Before each turbine chamber is a gate 23 feet wide by 15 feet high, operated by hydraulic pressure from a hand lever device Turbines of the Francis type, nine in number are used working at 107 r p m., and giving each 3,000 horse power maximum On the turbine shafts in the room above the main alternators are mounted The hyrdaulic work includes a by pass around the turbines, to take off part of the water when necessary, and thus to regulate the level without operating the main gates An extensive steam plant using Thomson-Houston Curtis turbines is used as a standby The present station supplies current for Bordeaux and other places.

The Determination of Standard Time*

How the Astronomer Sets Your Watch for You

By C H Gingrich

ALTHOUGH Astronomy from the earliest time to the present has had a host of ardent and enthusiastic students and although scarcely a person can now be found who is not profoundly impressed and deeply interested in the transcendent beauty of the sky if his attention be called to it especially so if he have an opportunity to examine through a telescope the numerous objects in the sky that are invisible to the naked eye yet very few know anything very definite about the nature and methods of work at an observatory It is almost universally true of visitors who come to our observatory that the thing in which they seem to feel the keenest interest is the method by which accurate time is obtained This indeed is quite the natural thing for every one many times each day has occasion to think of time and this then is the point of closest contact that most persons have with the science of Astronomy

Since day and night are of necessity determined by the rising and setting Sun, the opinion is very general among persons who have not inquired into the subject, that time is taken directly from observations made of the Sun We have some time heard the phrase honest as the Sun the value of which as a figure of speech is greatly diminished when the exact movements of the Sun are understood Of course the movements of the Sun extending through the period of a year are very definite, and of the utmost precision, but they are quite variable from day to day It is not then from the Sun, but from the distant and so called fixed stars that time is taken This at first thought would seem to introduce more uncertainty than ever for the most casual person will observe that the sky is not the same at all seasons of the year The constellations that appear at night in winter for example are not the ones that appear in summer and the positions of a star in the sky at the same hour in two successive nights are not the same It need scarcely be said that the constellations such as Orion, that are so brilliant during the winter months in this latitude pass overhead during the summer months in the day time and are consequently rendered invisible by the brightness of the Sun

In order to reconcile this apparent variability with the very exact and accurate nature of the time that railroads and numerous other enterprises require for their successful operation it is necessary to call attention to the fact that there are four kinds of time whose characteristics and interrelations should be clearly understood They are Sidereal Time True Solar Time Mean Solar Time and Standard Time

Sidereal time as its name suggests is star time If at a certain instant a given star is on the meridian then after twenty four Sidereal hours have elapsed the same star will again be on the meridian Since the distant stars keep the same positions in space because their tremendous distances from us render any change imperceptible in long period the regularity with which a given star comes to the meridian is dependent only upon the uniform rotation of the Earth on its axis

Although there are forces operating to change the time of rotation they are so small and opposite in effect that they are negligible The meteors that strike the Earth and the tides are two forces that tend to retard the rotation and lengthen the period and on the other hand we have the contraction of the Earth and the constant erosion of soil from higher to lower altitudes, forces that tend to accelerate the rotation and shorten the period By taking all such forces into consideration it is definitely known that their resultant could not change the period of rotation by as much as one second in ten thousand years In the great complexity of changes that are going on about us we have the period of rotation of the Earth on its axis as an unvarying quantity and it must serve us as our starting point in the exact determination of time

The Sidereal day then is the time that elapses between two successive passages of a star across the meridian and is divided into twenty four hours Likewise the true solar day is the time that elapses between two successive passages of the Sun across the meridian The true solar day is longer than the sidereal day because of the fact that the Sun has a motion toward the east that stars do not have This motion is due to the Earths revolution about the Sun in one year The relative motion of the Earth to the Sun will be the same for our purpose if we consider the Earth as fixed and the Sun as moving about the Earth If we suppose then that the Sun and a given star arrive at the meridian at a certain instant, we know that after twenty four sidereal hours the star will again be on the meridian, but in the meantime the Sun will have moved eastward and some minutes more must pass before the Sun arrives at the meridian An idea of the quantity of this motion of the Sun toward the east may be formed from the fact that a complete circuit of the sky is made by the Sun in a year This motion however is not uniform, because the Sun moves not in a circle about the Earth as a center but in an ellipse having the Earth at one of the foci The angular motion then is variable and the True Solar day, though always longer than the Sidereal, varies from 3 minutes 35 seconds in Sidereal time longer in September to 4 minutes 26 seconds longer on December 22nd We ordinarily think of December 22nd as the *shortest* day, when in another sense it is really the *longest* day in the year Because of this irregularity in the length of the True Solar day it would be very difficult, if not entirely impossible to construct a clock that would constantly show True Solar time

This leads then to the introduction of Mean Solar time. We suppose a Sun that starts with the real Sun, and travels in the plane of the equator toward the east a uniformly equal distance each day and just rapidly enough to complete the circuit in the same time as the real Sun does so that the imaginary or fictitious Sun arrives at the starting point at precisely the same time as the real Sun This imaginary Sun at certain seasons comes to the meridian in advance of the real Sun and at other seasons after it. Since its angular motion is uniform, the time between two successive transits of the imaginary Sun across the meridian will always be the same This Mean Solar day is 24 hours 3 minutes 56.556 seconds long in Sidereal time This period is divided into twenty four solar hours, and this is the hour that is indicated on the dial of the ordinary clock The further modification of Mean Solar time to obtain Standard time is for convenience only and not caused by any necessity in the time itself, nor in the difficulty of constructing clock, for Mean Solar time is uniform just as is Standard time A moment's thought will show that if time as shown by clocks were the Mean Solar time then all places on the same meridian would have the same time, but a place a few miles east or west of a given place would have different time This time is sometimes kept and is called local time, but endless confusion in travel would result if railroads were operated by local time. Hence in certain belts the time is fixed by the time of a meridian near the middle of the time belt These belts are 15 degrees wide, so that in passing from one belt into another the time changes abruptly by one hour These belts, moreover, are arranged so that time in them is an integral number of hours from Greenwich. By this arrangement the error in time at any particular place will not exceed one half hour

Standard time then is the kind that is ultimately sought Obviously there is no object in the sky that can be observed for Standard time directly Nor, indeed can Mean Solar time be determined by direct observations, for the Sun which determines it is purely fictitious However, the real Sun may be observed directly, and then since the relative positions of the real and the fictitious Sun can be computed for each day, and indeed, are tabulated in the *American Ephemeris* and also in other almanacs in the form of equation of time. True Solar time, as observed, may be changed into Mean Solar time, and this in turn may easily be converted into Standard time, provided the longitude of the place at which the observation was made is known Various methods of observing the Sun may be used, one of which is by use of the sextant, which cannot be made very accurately, and another is to use a permanently mounted transit instrument, and to observe the moment when the Sun is on the meridian The difficulty here lies in the fact that the Sun is so large that it is difficult to decide the exact moment when the center of the Sun is on the meridian Because of these practical difficulties the method of observing the Sun is not very often followed The method usually followed, and the one used at Goodsell Observatory, is by observing the star and it is the method which we use here that I desire to describe.

To determine time is really to determine the clock error It is not essential for that purpose that the error be large or small, though as a matter of fact the error is usually less than one minute. For if it were greater than that, it would be an easy matter, after a single determination of the error to move the hands until the error was made less than one minute

In order to determine the clock error two instruments are essential, first the transit instrument, and second the chronograph. The clock is provided with an escapement which breaks an electric circuit every two seconds. This circuit connects the clock with the chronograph which has as its essential part a cylinder which rotates once each minute About this cylinder is fastened a sheet of blank paper upon which a pen traces a continuous line as the cylinder rotates. The armature that carries the pen is released when the clock breaks the circuit, so that there is a series of offsets in the line that the pen traces, separated by exactly two seconds The escapement wheel is so arranged that the circuit is broken also at the fifty ninth second, so that one can tell by the record where the minute ended The minute during which the record was started is marked on the sheet, so that, by counting the minutes from that time one can determine any particular minute and second during the time through which the record extends

The transit instrument is mounted so that it is free to move only in one plane, namely in the plane of the meridian The reticle of the transit contains a number of wires which are illuminated, and which are located symmetrically with respect to the center If the wires are not exactly symmetrical with respect to the center, the error of instrument in this particular is found by trials and a correction is introduced into the reduction to account for that error The observer at the transit holds in his hand an electric button which, when pressed, breaks the circuit, and releases the armature, which carries the pen, in the same way as an escapement wheel in the clock does, so that he may insert offsets in the line traced by the pen in addition to those inserted by the clock regularly at the end of each two seconds. The transit instrument is also supplied with a graduated circle which serves as an indicator for setting the instrument at the proper altitude for the star to be observed.

With this equipment one is ready to proceed with the actual observation. Assuming that the error of the clock is small, he can tell from the clock what particular stars are near the meridian and will transit the meridian during the next half hour, more or less, during which his observations are to extend. If he had no indication at all as to the error of the clock, he would be obliged to observe some bright known stars and from these by perhaps rather rough approximation reduce the error until it becomes less than one minute Where such observations are made periodically the clock error is kept small. Then he knows what stars are about to transit the meridian, since the Sidereal time indicates the right ascension of the zenith at any time, and it is necessary only for him to look into any star catalogue and select such stars as have right ascensions a few minutes greater than the Sidereal time. From the same catalogues he can get the declinations, and knowing the latitude of the place from which he is observing, the altitude in which the star will cross the meridian may easily be determined Again at places where such observations are made regularly, a list of time stars is prepared and kept permanently This list shows the right ascensions of the star which is, indeed, the Sidereal hour when the star will be on the meridian, the declinations zenith distance, circles, setting for the instrument to be used, and usually the magnitude, so that the observer may have the brightness as a check on his selection of the star, for it is quite possible that more than one star may appear in the field of the transit. This list of stars is so chosen that in the course of an hour or less one can always find stars in the northern sky as well as near the zenith, near the equator and in the southern sky The reasons for such a selection will become apparent when we come to speak of the reductions of the observations.

When everything is in readiness, the observer selects a star that will cross the meridian in two or three minutes sets the instrument according to the position defined for this star in the star list, and takes his position at the instrument, having the electrical push button in his hand He may move the eye-piece to one side and thus get the star in view some time before it crosses the wires, but in any case the star swings into view, moving quite rapidly or very slowly, according as the star is near the equator or near the pole He selects the middle wire and a certain number on each side of it as those with respect to which he desires to record the transits As the star transits them he pushes the button and interpolates his record on the chronograph sheet upon which the clock is making its continuous record He then selects another star and records its transits in the same way Usually four or five stars are observed and recorded in this way, care being taken that the stars chosen shall not all be in the same region of the sky These then constitute a time set.

After this comes the reduction of the observations By reading the records for each star from the chronograph sheet by means of a scale designed for that purpose, and taking the mean, the clock time of the transit of the star across the meridian is found to the tenth or even to the hundredth part of a second The right ascension of the star, as given in the *American Ephemeris* at intervals of ten days throughout the year, is the actual time at which the star crossed the meridian If there is any discrepancy between the actual time and the clock time, this discrepancy may arise from several sources. If the transit instrument were in perfect adjustment the discrepancy would be entirely due to the clock error, but this is very seldom the case. However, there is no uncertainty on this point since the corrections to the instrument are carefully determined from time to time. Four quantities are recognized as contributing to the discrepancy between the actual time of transit and the clock time as shown by the chronograph record; first and most important, the clock error itself, second, the azimuth error, third, the level error, fourth, the collimation error The first is the quantity that is sought ultimately and is taken to be the discrepancy that remains after the effect of the other three has been removed. The second is obtained from the observations themselves and results from the fact that the rotation axis of the transit is not exactly east and west. If one imagines this to be exaggerated much beyond any possibility in any well mounted instrument he will easily see the effect. For instance, suppose the support for the east end of the rotation axis to be one foot north of the support for the west end, then it is easily seen that, when the instrument is directed toward the south, it will point considerably east of south, while

* Reprinted from *Popular Astronomy*

if directed toward the north it will point west of north. This error may be very small, but must be considered. The third, or level error, is determined by the hanging level at each observation. This is due to the fact that one end of the axis may be higher than the other, which condition would also tilt the instrument out of the plane of the meridian. This varies slightly and must be determined each time. The fourth, a collimation error, is due to the fact that the mean of the eleven wires may not be exactly in the collimation plane, the plane which is described by the line, called the collimation axis, from the optical center of the object glass perpendicular to the rotation axis, as the telescope is rotated. Since the parts that affect this error remain relatively unchanged for long periods of time, it is necessary to determine this error once in two or three months.

These quantities are connected in the following relation:

$\Delta\theta + Aa + Bb + Cc =$ actual time — clock time of star transit, where $\Delta\theta$ is the clock correction, A, B and C are known quantities depending upon ϕ, the latitude of the observer, and δ the declination of the star, and are computed beforehand, and a, b and c are respectively the factors introduced by the azimuth, level and collimation constants. We have seen that c remains unchanged for long periods and hence is a known quantity. We have also seen that b is determined at each observation by the hanging level and consequently is known for each set of time stars. We have then four or five equations, depending upon the number of stars observed, of the form given above in which $\Delta\theta$ and a remain as yet undetermined. We select the two that are most diverse, which will usually be the most northern and most southern stars, since they will be oppositely affected by the azimuth error, and subtract the one from the other, thereby eliminating the $\Delta\theta$, and obtaining an equation from which a may be found. Applying this value of a to the four equations we get from each one a value of $\Delta\theta$. These separate values serve as a check upon the accuracy of the work and should agree very closely. Their mean is then taken as the value of $\Delta\theta$, the clock correction. Sometimes an additional correction, namely, the personal equation of the observer, is added, and when extreme accuracy is desired a greater number of stars is observed and the reductions are made by the method of least squares. However, the method outlined here gives results that may be depended upon to the tenth of a second. It might be said that the clock is not set each time that its error is found, for obviously the clock is quite as serviceable if the error is known as if it should show exactly accurate time.

This then gives accurate Sidereal time, and it remains now to show how this is converted into the Standard time which is the time we use. Since the Sidereal minutes are shorter than the Standard time minutes, the seconds do not beat together on the two clocks, but at intervals of approximately six minutes they do beat together momentarily and then the Sidereal clock beat precedes the Standard clock beat again. By noting the second on each clock when this coincident beating occurs we get a clock comparison. Now the Sidereal time shows the time since *Sidereal* noon, and this interval may be converted into an equivalent Standard time interval by tables that are constant. Also we find tabulated in the *American Ephemeris* the mean time of Sidereal noon for each day of the year. If then we add to the mean time of Sidereal noon on the day in question the interval of time that has elapsed since Sidereal noon we have the correct mean time for the instant at which the comparison was made. This is changed into Standard time by adding or subtracting the distance of the place in longitude expressed in hours from the meridian which fixes the time in the belt. This must be added for places west of the Standard meridian and subtracted for those east. The difference between this time and the reading of the clock at the time of the comparison indicates the correction to the Standard clock.

The correction cannot be effected by hand, since it frequently is only a few tenths of a second. The correction is made by a temporary magnet over which swings a permanent magnet, which is fastened to the pendulum. The temporary magnet is polarized by a current of electricity which may be sent in either direction and thus make the pole nearest the permanent magnet positive or negative as desired, and thereby accelerate or diminish the rate of the pendulum during the time when the temporary magnet is operating. The effect is sufficient to change the clock by about one hundredth of a second per minute, so that very minute changes may be made. This clock then may be used for sending time signals, as its error is reduced to zero.

Precautions in the Use of Explosives

IN a circular published by the Bureau of Mines and written by Clarence Hall some excellent precautions are given for the use of explosives, notably so-called permissible explosives, which are used in coal mines. Permissible explosives, it may be said by way of explanation, give a short and relatively cool flame, are less likely to ignite inflammable gas or coal dust than is the longer and hotter flame of dynamite, or the longer and much more lasting flame of black powder, and are intended for use in those coal mines where the presence of such gas or dust may render a mine explosion possible.

According to the circular mentioned the following precautions should be taken to reduce the risk in storing, thawing, handling and using explosives in coal mines:

(*a*) PRECAUTIONS TO BE TAKEN IN THE STORAGE OF EXPLOSIVES

Don't store detonators with explosives. Detonators should be kept by themselves.

Don't open packages of explosives in a magazine.

Don't open packages of explosives with a nail puller, pick, or chisel. Packages should be opened with a hard wood wedge and mallet outside of the magazine and at a distance from it.

Don't store explosives in a hot or damp place. All explosives spoil rapidly if so stored.

Don't store explosives containing nitroglycerin so that the cartridges stand on end. The nitroglycerin is more likely to leak from the cartridges when they stand on end than it is when they lie on their sides.

Don't repair a magazine until all explosives are removed from it.

(*b*) PRECAUTIONS TO BE TAKEN IN THAWING EXPLOSIVES

Don't use permissible explosives or other explosives that are frozen or partly frozen. The charge may not explode completely and serious accidents may result. If the explosion is not complete the full strength of the charge is not exerted and larger quantities of harmful gases are given off.

Don't thaw frozen explosives before an open fire, nor in a stove, nor over a lamp, nor near a boiler, nor near steam pipes, nor by placing cartridges in hot water. Use thawers, such as are furnished by the manufacturers of explosives.

Don't put hot water or steam pipes in a magazine for thawing purposes. Where large quantities of explosives are used a special thaw house should be built large enough to hold the quantity of explosives needed for a day's work.

(*c*) PRECAUTIONS TO BE TAKEN IN HANDLING DETONATORS AND EXPLOSIVES

Don't carry detonators and explosives in the same package. Detonators are extremely sensitive to heat, friction, or blows of any kind.

Don't handle detonators or explosives near an open flame.

Don't expose detonators or explosives to direct sunlight for any length of time. Such exposure may increase the danger in their use.

Don't open a package of explosive until ready to use the explosive, then use it promptly. All explosives are injured by exposure to the action of the air.

Don't handle explosives carelessly. They are all sensitive to blows, friction and fire.

(*d*) PRECAUTIONS TO BE TAKEN IN USING DETONATORS AND EXPLOSIVES

Don't use more than $1\frac{1}{2}$ pounds of any permissible explosive for one shot in a coal mine. No explosive is safe if used in large quantities under ordinary coal mine conditions.

Don't use a detonator (blasting cap) or electric detonator of less strength than that prescribed by this bureau. The explosive may not explode completely, thus reducing the work done by the shot and causing the same dangers that come from the use of frozen explosives.

Don't crimp a detonator (blasting cap) around a fuse with the teeth. Use a cap crimper, which is supplied by any manufacturer of explosives.

Don't economize by using a short length of fuse. Such practice is liable to result in a shot going off too soon.

Don't fire a charge of any explosive in the presence of fire damp. A fissure or crack in the coal or rock may bring the gas and air mixture directly to the explosive. Such fissures are most likely to be found in driving or breaking through. If gas is found when such a fissure is cut, clean the gas out before shooting. If the gas can not be cleaned out, cut through with the pick and fire no shots.

Don't use in a gaseous coal mine any fuse or other device which emits flame or sparks. The end or side spitting of a fuse or squib may ignite gas. Electric detonators give better results and are safer.

Don't tamp the explosive with coal cuttings or slack or any combustible material. Use damp clay, which is safer and better, and have this stemming fill the drill hole to its mouth.

Don't use a metal tamping rod. Even a copper tipped rod is not to be recommended. Use only wooden rods.

Don't use two kinds of explosives in the same drill hole. When such a charge is fired chemical changes may take place that may make each explosive less safe than if used alone.

Don't return to the face until at least five minutes after a shot has been fired. All explosives tested to date, including black blasting powder, yield inflammable and poisonous gases. Field tests made by this bureau in bituminous-coal mines indicate that some of the coal in the drill hole helps to form such a gas, and that a shot liberates inflammable gases from the coal itself. The liberated gases escape slowly from the cracks made in the coal sometimes for several minutes, but finally all the gases resulting from the shot diffuse in the mine air, and with proper ventilation are carried away.

Don't return to the face for at least one-half hour after a misfire. Hangfires and misfires are most likely to happen when squibs or fuse are used.

Don't attempt to draw nor to dig out the charge in case of a misfire. Some authorities believe that the great disaster at Courrières, France, in which 1,100 men lost their lives, was caused by a miner striking with his pick a cartridge he was digging out. Drill and charge another hole at least 2 feet away from the hole that misfired. After the coal has been brought down look carefully for any unexploded material.

Don't leave any detonators or explosives in a mine over night. The mine air usually contains moisture and is bad for all explosives.

Don't charge or load any hole which has not been properly placed or has been drilled on the solid.

Don't light the fuse of dependent shots at the same time the first shot is lighted. The inflammable gases from the first shot and the gases liberated from the coal itself, together with the coal dust in the air, may ignite from the spitting of the fuse of the dependent shots. The place for a following shot and the size of the charge to be used can be judged better after the first shot has been fired.

Don't expect to get satisfactory results with a permissible explosive or any explosive when a miner uses it for the first time. The most coal will be won for each pound of explosive used and the safety will be greatest if all shots are loaded and fired by men especially trained for this work. The practice of firing all shots by electricity after the men have left the mine is growing in favor.

Don't think the use of permissible explosives can take the place of other safety precautions in mines and thus neglect these other precautions.

TABLE OF CONTENTS

INDEX OF INVENTIONS

For which Letters Patent of the United States were Issued for the Week Ending February 28, 1911

AND EACH BEARING THAT DATE

[See note at end of list about copies of these patents]

Acetylene tetrachlorid, producing, Hoefer & [illegible] ... [illegible]
Adding machine, G. R. [illegible] ... [illegible]
[illegible] ... [illegible]
[illegible] ... [illegible]
[illegible] ... [illegible]
Aeroplane, E. K. A. Baumann ... 985 176
Aeroplane, A. W. Scheef ... 985 375
Aeroplane, M. B. Dunkle ... 985 666
Aeroplane construction, J. Rooney ... 985 373
Agricultural implement, P. G. Conover ... 985 568
Air brake attachment, Fagett & Penington ... 985 202
Air brake hose coupling, F. & V. J. Roberts ... 985 551
Alimentary product and making the same, S. I. Moser ... 985 621
Ammonium perchlorate, producing, O. B. Carlson ... 985 724
Animal catcher, V. Ramsbud ... 985 206
Animal trap attachment, R. A. Shaw ... 985 553
Anvil attachment, O. H. King ... 985 262
Arch support, L. Durieu ... 985 [illegible]
Armature housings, manufacture of, C. A. Pfanstiehl ... 985 700

Stellar Magnitudes*

The Problem of Measuring the Brightness of a Star

By J E Maybee

It is an oddity of terminology and a survival of immemorial custom that a term expressive of size is used to designate the brilliancy of a star *Metaphorical language* seem almost out of place in an exact science like astronomy yet to the ordinary dabbler in astronomy the term magnitude used to express light giving power does not appear unapt for we are well accustomed to speak of a man of brilliant intellectual or moral acquirements as a big man and to the non scientific undoubtedly the biggest and most important point about a star is its relative brilliancy of appearance So we shall accept the term magnitude as expressing the luminosity of a star as viewed from our earth

The term is as already suggested an old one and comes to us from Ptolemy (140 A D) In the Ptolemaic cosmogony as is well known the stars were supposed to be set in a crystalline sphere and were all at the same distance from the earth It was not an unnatural assumption then that differences in brightness indicated difference in size The final triumph of the Copernican theory of the universe resulted in the passing away forever of *this* theory of stellar magnitudes but another quite as erroneous took its place namely the assumption that all stars are of the same intrinsic brilliancy and that the *difference in their appearance* is due simply to differences in their distances from us We now know that some of the most brilliant of the stars are comparatively distant and that others relatively dim are among our nearest neighbors We also know that there are dark stars Algol's dark companion for example and it is reasonable to assume therefore that stars vary not only in their distances from us but in their intrinsic luster as well

Stellar photometry is the branch of astronomical science which undertakes the task of determining the relative apparent brightness of the stars and any variations therein

It is an important branch of astronomical work for when combined with determinations of parallax and spectroscopic analysis it enables us to get an approximate *idea of the real sizes of stars* For it is evident that given a star which differs from another in brightness its distance and the *quality* of the light being the same the difference of brightness gives at once a measure of the relative sizes of the two Or if the brightness and quality of light are the same but the distances different the two stars vary in size directly as the square of the distance

Working along such lines it is found for example that though 61 Cygni magnitude 5 4 distance 6 5 light years, is only one seventh the solar mass Arcturus magnitude 0 24, distance 127 to 160 light years is possibly equal to a million suns

Having arrived at an idea of the meaning of "magnitude" as applied to stars, and of the importance of stellar photometry we shall now consider on what lines *stellar magnitudes are determined* Our present system of expressing magnitudes possesses several incongruities In the first place the smaller the magnitude the brighter the star There would be no great trouble about this however were it not for the fact that some stars are brighter than first magnitude Hence we have the anomaly of stars of 0 magnitude and even magnitudes Some further confusion is due to the fact that the eye does not perceive the actual ratio of brightness between two stars For instance, a star of the 3 5 magnitude might be supposed to be a mean between a star of the sixth magnitude and a star of the first magnitude. But not so a star of 3 5 magnitude is 12 6 times as bright as a star of the sixth magnitude And a star of the first magnitude is 100 times as bright as a star of the sixth magnitude and therefore 8 times brighter than a 3 5 magnitude star

Following this out it appears that if the brightness of a sixth magnitude star be called 1 that the brightness of a fifth magnitude star is 2 512 of a fourth magnitude star 6 3, of a third 15 8, say 16 of a second magnitude star almost 40 and of the first just 100 Magnitude 0 0 is represented by 251 2 and magnitude —1 by 631 In each case the brightness relative to the sixth magnitude star is found by raising 2 512 to a power represented by the difference in the magnitudes It follows then that to determine how many times one star is brighter than another you subtract the lesser magnitude from the greater and raise 2 512 (the light ratio) to a power represented by this difference This is easy when dealing with whole magnitudes but rather more difficult when stars differ by fractions of a magnitude But logarithms help us out of the difficulty The logarithm of 2 512 is 0 4 and we may raise 2 512 to any desired power by multiplying 0 4 by the index of the desired power which gives us the logarithm of the desired power and a reference to a table of logarithms will give the number corresponding to the logarithm so found which represents the number of times the lower magnitude star is brighter than the higher magnitude star Let us take a case Regulus is of a magnitude represented by 1 34, Sirius is of a magnitude represented by —1 58 (Miss Clerke) Subtract —1 58 from 1,34 and we get 2 92 Multiply 2 92 × 0 4, the logarithm of 2 512 the light ratio, and we have 1 168, and this is the logarithm of 14 72 so that Sirius is 14.72 times as bright as Regulus It should be clear then that the actual difference in brightness between two stars is much greater than it appears to the naked eye, for the eye is *not impressed in proportion to the actual difference*, but only in proportion to the logarithm of that difference, or, to put it differently stars which to the eye appear to form an arithmetical progression in brightness, in reality form a geometrical progression This will explain why a photographic tyro is so often deceived in the photographic value of the evening light His eye may tell him that the light is approximately midway between two known standards, and therefore he may decide on an exposure say of double that he would give under the brighter standard, while in reality the actinic value may be so much lower that eight times the exposure is necessary to proportionately affect the plate

The problem of stellar photometry is not an easy one as there are so many difficulties in the way of getting uniform conditions for observing For instance in the country stars look much brighter than they do in the city and on a mountain brighter than they do in the level country W H Pickering also thinks the seeing is much better nearer the equator than in the temperate zones Stars near the zenith also appear brighter than when near the horizon, and as some stars to an observer in a given station never rise far above the horizon his observations will give a lower value to the brightness of such stars than if they were observed near the zenith Thus observations of star magnitudes must have a correction applied reducing them to standard distance above the horizon if they are not observed under similar conditions Further eyes differ in their sensitiveness to light and thus one observer may get results different from those of another

The color of a star also may affect the results as some eyes are more senstive to one color than another Another curious thing is that if we take a green light and a red light of equal intensity and either double or halve the intensity they will no longer appear equal to the eye When the intensity of both is doubled the red will appear the brighter and when halved the green will appear the brighter It is also to be remembered that the atmospheric absorption for the different parts of the spectrum is not the same When all these things are considered it is no wonder that the photometric determinations of different observers vary

It will be interesting I think to consider the number of the stars of different magnitudes Here again doctors differ but I have used the figures given by Todd (1897) I = 20 II = 65 III = 220, IV = 500, V = 1 400 VI — 5 000 total 7,205 The number increases up to the tenth magnitude by a sort of rough geometrical progression the stars of a given magnitude being from 3 to 3 75 times more numerous than those of the next higher (i e brighter), so that there are about 720,000 stars of the tenth magnitude After that the ratio decreases so that it is probable that in the first 16 or 17 magnitudes there are not more than about 100 000 000 stars

A study of the total light giving power of stars of the different magnitudes reveals some unexpected results It will be remembered that the brightness of stars of different magnitudes increases in a geometric progression 2 512 being the ratio but the number of the stars of the different magnitudes from the first downward to 10 increases as above stated in a geometric progression in which the ratio is from 3 to 3.75 consequently as the magnitude decreases the total light increases One curious result of this is that we get over twenty times as much light from stars we cannot see with the naked eye than from those we can see

The estimates of the total light received from the stars vary widely Newcomb's experiments would put it in the neighborhood of about $^1/_{80}$ of the light of the full moon Prof Young put it as high as $^1/_{60}$ Newcomb's estimates up to the tenth magnitude are interesting and I shall quote them Taking the light of all those of the first magnitude as unity 1st magnitude = 1; 2nd = 1 4; 3rd = 2; 4th = 2 8; 5th = 4; 6th = 5 7; 7th = 8; 8th = 11 3 9th = 16; 10th = 22 6

Stars from magnitudes 1 to 6 are naked eye stars, and their proportion of the total light is 16 9 units, only about $^1/_7$ of the total light up to the 10th magnitude,

As we estimated that the naked eye stars give about $^1/_{30}$ of the total light received from all the stars and the stars down to the 10th magnitude give five times as much, it is evident that all the *stars must* give four times the light of those down to the 10th magnitude, and consequently the stars below the 10th magnitude give three times as much light as those from 1st to 10th

It is very clear then that we would not suffer a very serious diminution of sky light at night if all the stars that delight our unaided eyes were blotted out, while the extinction of the telescopic and photographic stars would be a very serious deprivation Another instance, by the way of the importance of unseen things Who can say but that higher senses or a better development of our present senses might not reveal other and more important unseen influences than the light of the stars,

I might say in parody of Hamlet "There are more things in heaven and earth, Horatio, than are seen by your astronomers."

I need say little about the ordinary methods of observing star magnitudes.

One is by naked eye comparison, but more important scientifically are the extinction method by means of a *wedge of neutral tinted glass, and the equalization* method in which the polariscope is employed.

The photographic method is less employed, and being also less well known deserves fuller mention

Photography has been probably the most important of the sister arts or sciences which have been pressed into the service of astronomy It has enabled the astronomer to penetrate into the depths of space far beyond the ken of our largest visual telescopes, it has made possible the charting of the heavens in a manner impossible by the laborious method of visually observing and charting individual stars, and now it comes to our aid in stellar photometry

When, however we consider that what *we* see in a star and what a sensitive dry plate sees are quite different things, it is at once evident that photographic magnitudes are not always strictly comparable with visual magnitudes

The blue end of the spectrum and the ultra violet most affect a dry plate, while our eyes give greater value to the orange and red end of the spectrum and it is impossible to make our plates exactly take the place of eyes even by the use of colored screens and orthochromatic plates Still photographic estimations of the stellar magnitudes have their value since the results in the case of bright stars follow very closely the visual estimates, and in any case we have a record of the relative standing of the stars observed as regards the blue and ultra violet rays they emit

Photographic magnitudes are estimated in different ways. The first is by observing the effects of irradiation To make this method clear to you consider an analogy

If I throw a small stone into a pool of soft mud it will make a little splash If I throw in a large stone it will make a big splash, and stir up the mud in a much wider circle than did the little one Now weak light and strong light produce much the same effect on a photographic plate as did the stones on the mud

Most view photographers have had good pictures of interiors spoiled by the strong light from some window making a "halo" round about the window frame A point of light from a star acts in the same way and if the exposure is long enough the light is reflected from particle to particle of the emulsion in such a way that the star image is enlarged to a circle It is evident that bright stars make a greater splash as it were on the plate than faint stars, and so by measuring the diameters of these images we can estimate the relative photographic magnitudes of the stars that made them

Another plan is to move the plate slightly inside the focus of the lens, giving the star the appearance of a luminous disk The luminosity of these disks will vary of course with the brightness of the stars observed, and by measuring the opacity of the silver deposits formed on the plate the relative magnitudes of the stars observed may be estimated

The usual method of observing is to photograph the desired stars when they are at the altitude of the pole and then on the *same* plate and with the same exposure photograph the pole star and a certain sequence of standard stars around it The standard stars and stars to be observed are easily identified by taking separate photographs of each, superimposing these on the double-exposed plate and marking the desired stars The double exposed plate may now be examined and the magnitudes of the observed stars estimated by comparison with the stars of the standard sequence.

Attempts have been made to secure an absolute scale of photographic magnitudes You will have noticed that in the above method the magnitudes are obtained by comparison with stars of previously determined magnitudes. This is not always a very convenient method, and besides some day our standards may have changed their brightness If, therefore, we can adopt a standard of comparison which can at any time be reproduced by laboratory experiments a great advance has been made, for any observer in the distant future can always compare our determination of magnitudes with his own, as the possession of the data is all that is necessary to the reproduction of the standard.

Messrs. Parkhurst and Jordan, of the Yerkes Observatory have recently tried a method of obtaining absolute magnitudes with much success.

Their process was to illuminate different parts of a photographic plate with the light passing through a number of holes varying in size in a regular ratio and representing differences in illumination expressible in stellar magnitudes Plates have been produced in this way, and by comparing them with one of Pickering's photographic wedges the absorption curve of the wedge could be plotted and the wedge scaled in stellar magnitudes. Star images are then photographed out of focus and the plates compared in a photometer with the wedge and the magnitudes of the stars determined according to the effect their light had had on the plate. The effect of the stars on the plate is thus comparable with the light passing through holes of different diameters.

This sounds quite simple, but in that it is like a great many other astronomical observations, which are very

*Journal of the Royal Astronomical Society of Canada.

simple if only rough approximations to accuracy are required, but which require all the refinements ingenuity can suggest to avoid or eliminate errors and secure those extremely accurate results which modern astronomy demands.

The originators of this method deem it useful for the measurement of light curves of variables of the Algol type and of short period variables generally

In this article the treatment of the subject has necessarily been general rather than specific, as my aim has been to give as complete an outline as possible of the whole subject and to bring together general information now unobtainable by the amateur except by reference to a considerable number of standard works and scattered papers

The Relation of Light to the Growth of Plants

How Colors Affect Vegetation

By Benjamin C Gruenberg

It has long been known that in the carbon fixation by green parts of plants the red rays of the solar spectrum seem to produce maximum results This is apparently not due to the difference in wave-length between the blue or violet rays and the red rays, but rather to the difference in the relative energy intensities of the different colored rays used in the earlier experiments With equal amounts of energy supplied, the green plant will decompose carbon dioxide as readily with light from one end of the spectrum as with rays from the other These results are however partly invalidated by the further fact that it is impossible to measure the quantity of light energy actually utilized by the chlorophyl of a leaf Since experiments have to be conducted with the live plant, the measurements heretofore have consisted of determinations of the total amount of light falling upon the surface of the leaf But different tissues of the leaf will absorb different rays in varying proportions, and it is impossible to tell what portion is absorbed by the chlorophyl bodies themselves These latter contain, in addition to the chlorophyl, other pigments, especially yellow substances that absorb blue and violet rays very strongly These pigments do not contribute to the decomposition of carbondioxid; a large portion of the blue-violet light is absorbed without being converted into chemical energy

Most of the investigators who have grown plants under lights of different colors have found a maximum of dry weight addition to the plants in connection with the red and yellow rays of the solar spectrum One or two however have found the maximum production at the other end of the spectrum According to Dr W Lubimenko of the Imperial Botanical Garden of Nikita in Russia, this apparent contradiction arises from the failure of earlier investigators to distinguish between the energy utilized by a plant in the decomposition of carbon dioxide and that used in the later stages of carbon fixation This botanist repeated a number of the earlier experiments, determining in each case the actual amount of carbon dioxide decomposed in a given time

Lubimenko used colored glasses whose actual color values were ascertained by means of the spectroscope from these he obtained a complete range of colors from the extreme of the visible violet to rays having a wave length of 0 700μ As a means of control he used plain white glass, single layers of paraffined paper and double layers of this paper As the monochromatic light filters varied as to the amount of light that they allowed to pass through the glasses were selected by means of comparative spectro-photometric tests and arranged to permit equal illumination for all segments of the spectrum The amount of light cut off by the paraffined paper was also measured by means of sensitive photographic paper it required 180 thicknesses of the paraffined paper to shut out completely the light of the sun The usual precautions were taken as to temperature sampling, etc The experiments were carried on in parallel for five different species, namely radish, bean pea, nasturtium and carrot.

The results, given in three tables, are summarized as follows:

An examination of the table shows that the maximum production did not in any case coincide with the maximum illumination the sunlight modified by one or two thicknesses of paraffined paper being more favorable to gain in weight It was also found that the relation between increase and light varied from time to time in the course of a plant s development Thus in the case of the radish the full light gave the maximum increase during the third week whereas during the seventh week this gave the lowest increase Of course the actual differences in weekly gains depended also upon the variations in amount of daylight from time to time

By comparing the results for the colored lights it may be seen from the table that the smallest gains as well as the minimum of energy absorbed was uniformly from the green light Under the green glass the plants frequently died before flowering The red light yielded in all cases a maximum of energy for the decomposition of the CO_2 but, with the exception of the bean all the plants gained weight more rapidly under the blue glass than under the red

The anomaly in these results is explained by Lubimenko by assuming that the light plays a double rôle in the work of photosynthesis A strong light is first active in decomposing the CO and in the synthesis of the first organic product but the further assimilation of this first product requires a light of lower intensity The amount of carbon fixation depends upon the energy that effects this assimilation of the materials elaborated by the leaves Accordingly the gain in dry weight that a plant makes will be determined by a number of factors in addition to that of light intensity The chlorophyl apparatus is capable of doing a certain amount of work but the actual amount of work done will depend also upon the needs of the organism The amount of work it is capable of doing is far in excess of the needs of the organism

Lubimenko also thinks it likely that the lights of different wave lengths particularly the red and the blue have specified functions in the photosynthetic process The red rays serve to break up the CO and water and to recombine the elements into the first organic product The other rays absorbed during this stage of the process are of no use whatever to the plant For the assimilation of the organic matter formed into the substance of the plant, there is then needed a light of low intensity It is here that the blue rays serve specifically Since it is probable that the chlorophyl is also functional in this stage, the absorption by the chlorophyl of the blue rays is explained

These suppositions of Lubimenko s are partly in general agreement with what has been long known about the physiology of carbon fixation and of plant growth Plants exposed to very intense light do not grow as well as they do under moderate illumination This is shown by the rapid elongation of the shoots of plants kept in the dark as well as by the bending of plants that are illuminated from only one side The plant in such cases bends toward the source of light not because "it seeks the light," but because the darker side grows more rapidly than the lighter side It is not necessary however to make the further assumption that the chlorophyl apparatus participates in the assimilation of the carbohydrates, or that light is essential to the process It is a well known fact that plant cells supplied with nutrition will continue to form new tissues in the dark This is seen not only in the growth of underground portions of plants or of growing layers under the bark of trees, etc, but also in the case of plants kept in absolute darkness, but supplied with nutrients

Illumination	Radish		Bean		Pea		Nasturtium		Carrot	
	Energy Taken Up	Increase in Dry Matter	Energy Taken Up	Increase in Dry Matter	Energy Taken Up	Increase in Dry Matter	Energy Taken Up	Increase in Dry Matter	Energy Taken Up	Increase in Dry Matter
White Light— Full illumination	100	100	100	100	109	100	100	100	100	100
One thickness of paper	88	116	90	119	91	108	82	113	82	101
Two thicknesses of paper	66	126	74	108	7	101	72	148	—	137
Colored Light— Red	22	5	16	26	84	30	3	15	20	4
Orange	18	2	9	12	21	22	30	9	1	
Green	1	0	1	0	2	0	4	8	0 2	
Blue	18	6	13	28	22	41	24	29	16	7

As a basis for comparing the relative amounts of energy taken up in the decomposition of CO, the actual quantity of the gas decomposed was determined For each of the seven conditions of light a specimen was prepared in a vessel containing a mixture of air and CO_2 having from 10 to 12 per cent of the latter These were exposed to the sunlight, and the amount of CO_2 remaining in each vessel at the end of one hour was ascertained The five species of plants experimented upon differed among each other with respect to the quantity of CO_2 decomposed in an hour by a given amount of leaf tissue exposed to direct sunlight, from 69 7 volumes in nasturtium, to 97.6 in the case of the carrot.

To determine the increase in dry weight, samples were taken from each lot at intervals of several days and the gain found by actual drying and weighing.

According to the theory of Baeyer, carbohydrates are formed by the polymerisation of formaldehyde which results from the decomposition of CO_2 and water In accordance with this theory experiments have been made to determine whether a green plant can derive any nutriment whatever from formaldehyde Bokorney succeeded some three years ago in getting water cress to grow under a glass jar over a solution of caustic soda containing small amounts of formaldehyde—that is to say in an atmosphere free from CO Indeed, in this experiment the assimilation actually proceeded without oxygen and without light!

It is possible also that the amount of CO that disappeared in these experiments of Lubimenko s is no certain criterion of the energy absorbed by these plants under normal conditions That is the fact that CO, was present in such large excess may have led to its decomposition out of proportion to the power of the plant to make carbohydrates At any rate it is possible to interpret these figures without assuming a specific function for the rays of short wave length

These results are not in complete harmony with those obtained from some experiments on sugar production carried out in Idaho during the past two years (Sci Am Supp No 1834, last page) where the maximum growth and productivity was correlated with the highest illumination This disagreement may be explained as due to the specific susceptibility or tolerance to light exhibited by different kinds of plants

Cathode Rays in Telephotography

Cathode rays are deviated by a magnet instantaneously This fact has been utilized by Dieckmann and Glage in the construction of a telephotographic receiver destitute of inertia A pencil of cathode rays is defined by a diaphragm having a fine perforation This pencil is acted upon by two pairs of electro magnets which displace it in two mutually perpendicular directions and which are operated by two current components determined by the movement of a stylus at the transmitting station The result is that the pencil of cathode rays imitates every movement of the stylus instantaneously and thus produces, in a plate of chalk or other fluorescent material a luminosity which appears to the eye as a continuous line comprising all the successive position of the luminous point In the construction of the transmitter an artifice which has long been used in telautography is employed to resolve the motion of the stylus into rectangular components and to translate these into current strengths

The following modification of the process has a certain practical importance The electro magnets operated by a small dynamo provided with a voltage regulator are so arranged that they throw the pencil of cathode rays into regular oscillation in a vertical plane Each vertical oscillation is followed by a small horizontal displacement so that the phosphorescent point describes a series of parallel lines very close together In this way the phosphorescent point explores, in about 1/10 second an area 3 centimeters (1 2 inches) square In consequence of the persistence of impressions on the retina, the entire square appears luminous The transmitter contains a square of the same size which is explored successively by little metallic brushes in synchronism with the receiver These brushes are connected to one pole of a battery the other pole of which is connected through the line wire to two coils which serve to deflect the cathode rays at the receiving station The other ends of these coils are grounded A pattern or stencil of sheet metal connected to earth is laid on the transmitting square beneath the little brushes which as they traverse every part of the pattern close the circuit so long as they rest upon the metallic portions When the circuit is closed the cathode pencil is deflected so that it does not fall upon the receiving screen consequently the phosphorescent point traces on the screen only those areas which correspond with the cut-out portions of the stencil The whole operation is repeated indefinitely and consequently the picture can be viewed as long as desired With this arrangement each element of the image is produced in 1/5000 second The inventors of this process intend if possible to utilize aerial electric waves for transmission in order to eliminate perturbations due to conductors — *La Nature*

Recent Finds in Archæological Research

It is reported from Naples that during the recent excavations at Pompeii there was discovered the petrified body of a young woman upon which were jewels of great value Among these are bracelets and necklaces and other jewels showing that this must have been a person belonging to the patrician class Two earrings each composed of 21 pearls arranged in clusters were especially remarkable Besides their intrinsic and artistic value, they have a great interest from an archæological standpoint, as no others of the kind have been found at Pompeii We also note that at Brescia there were lately discovered the remains of a small necropolis of the Roman epoch, and up to the present 22 tombs are uncovered These date from the time of Augustus They contained no human remains other than dust, however but some interesting objects were found among others, vases of different forms and bronze necklaces of fine workmanship All these objects are well preserved

The Natural Tunnels of Laos

A Chinese Subterranean Watercourse

Cammon, a province of Laos in French Indo-China contains many extensive beds of ancient limestone, bordered by dikes of lava which in several places have been perforated by mountain torrents in their impetuous descent to the Mĕ Kong river. There are seven of these natural tunnels or subterranean watercourses, having an aggregate length of about 12 miles, half of which has been explored by M. Macey of the French

DOWN-STREAM MOUTH OF THE NAM HIN BOUN RIVER TUNNEL

colonial administration who gives an account of his researches in a recent issue of *La Nature*. The chain of these tunnels having a total length of more than 4 miles, through which the largest stream flows, and the subterranean portion of the smallest stream more than one mile in length are still entirely unexplored. The tunnels of the streams Sĕ Bang Fai (2½ miles long) Nam Hin Boun (2½ miles) and Houci Khi Heup (1¼ miles), have been completely explored.

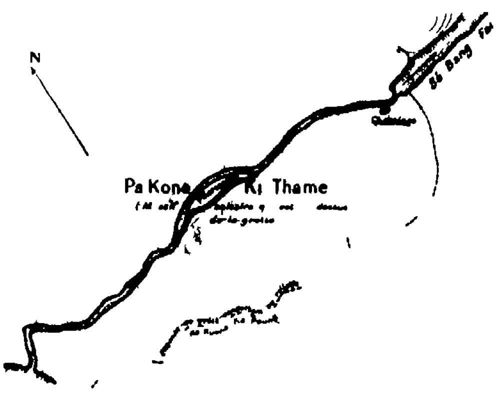
In August, 1904, a government steamer ascended the Sĕ Bang Fai to the down stream mouth of the tunnel 155 miles from the Mĕ Kong where a bamboo raft was constructed for the exploration of the tunnel. March was selected as the most favorable season for the exploration, as the stream was then lowest. In the shallower parts of the tunnel the depth of water varied from 2½ to 5 feet but in some of the depressions it was 26 feet. In places the stream was bordered by banks of sand or rock on which the explorers could walk with some difficulty towing the raft with a rope. Once a flood caused by a heavy rainstorm suddenly raised the level of the stream more than three feet and in a few minutes carried the raft several hundred yards down stream, undoing an hour's hard work. The storm continued 24 hours and three days elapsed before the water had subsided sufficiently to allow the explorers to proceed. Several rapids were also encountered. Twenty one hours of actual progress (in addition to the three days halt) brought the party to the double mouth of the tunnel. The lower opening was nearly submerged and the explorers made their escape by a perilous climb through the upper and larger passage. These openings are surprisingly small in comparison with many sections of the tunnel. Extremely high floods had left their marks on the face of the cliff 65 or 70 feet above the water or

DOWN-STREAM MOUTH OF THE SĔ BANG FAI RIVER TUNNEL

about 35 feet above the top of the upper opening. At this point the river is about 250 feet wide and is bordered by nearly vertical cliffs which extend upstream more than a mile on one side but only 200 yards on the other. Its source is some 50 miles distant.

The course of the Nam Hin Boun River is entirely confined to the alluvial plain of the Mĕ Kong and bends at a right angle in its underground part. This tunnel is frequently used as a subterranean waterway by the natives when the water is low. In the rainy season it is made impassable by a seething torrent which makes a terrific noise. In its underground course of 2½ miles the stream descends more than 100 feet by several rapids, which make portages necessary, even in going downstream. The voyage is made in light canoes, with bundles of bamboo attached to their sides, and occupies about 2½ hours in descending, and an entire day in ascending. The tunnel is very irregular in height and width, and exhibits a great variety of curves, straight lines and bends. At low water the greater part of the journey can be made on foot, on the sand banks and ledges of rock that border the stream, but the path is so rough that boats are generally preferred, even in going upstream, and the banks are used only at portages.

The Houci Khi Heup is a small stream, only 7 or 8 miles long which traverses a bed of limestone by a tunnel about 1¼ miles long, near its confluence with the Nam Hin Boum. This tunnel, which was explored in 1909 is the most interesting of all and no description or picture can give an adequate idea of the varied and majestic beauty of its masses of stalactites and stalagmites. In the dry season the depth of water varies from 16 inches to nearly 7 feet and part of the journey must be accomplished by swimming. In times of flood the water is 10 or 12 feet higher and the descent almost imperceptible, so that the tunnel can be traversed in canoes without any difficulty. The mouth by which the stream enters the tunnel is 65 feet high and 100 feet wide, but it is partly closed by a mass of rock, fallen from the cliff, so that the stream, which formerly divided into two branches inside the tunnel, is now confined to one of the channels. In floods some water forces its way into the other channel and flows on until it is stopped by a huge column of rock. This column is perforated



THE SUBTERRANEAN COURSE OF THE SĔ BANG FAI RIVER

by a bent passage about 7 feet in diameter but the floor of this passage is several yards higher than most modern floods, so that the water is stopped at this point, except in extremely high floods. The explorers walked, and even led horses through this passage. At the same point is an obliquely ascending passage which extends to the surface of the hill above. The stream emerges from the tunnel through a modest arch about 25 feet high. This tunnel of remarkable form and beauty can be traversed on foot in less than an hour in the dry season and by boat in a few minutes, in the rainy season, but several days may be enjoyably spent in exploring and studying its ramifications and lateral caverns.

Will Mankind be Compelled to Starve?

The threatened exhaustion of the world's supply of coal wood and iron is less alarming than the possibility that the earth may at no very distant epoch become unable to supply its greatly increased population with food. Already Great Britain and to a smaller extent, Germany and some other countries, are dependent upon the importation of grain. What can be done when this resource shall fail because the earth, as a whole, cannot produce sufficient grain for its needs?

At last year's meeting of the British Association for the Advancement of Science, in Winnipeg, the center of the Canadian grain trade, Major Craigie presented statistics of alarming import, showing that the population of Eastern and Central Europe has increased from 167 millions to 267 millions in the last 70 years, during which the area devoted to grain raising has actually diminished. In the years 1901-1905 the proportion of domestic production to consumption of grain was 20 per cent in Great Britain and Holland, 23 per cent in Belgium, 64 per cent in Germany and 80 per cent in Italy, and these countries annually imported more than four hundred million bushels of wheat. About half of this quantity came from Russia and other Eastern countries. As the average yield of wheat in non-European countries is only from 10 to 20 bushels per acre, an area of ten to twenty million acres was required to produce their exports to Western Europe.

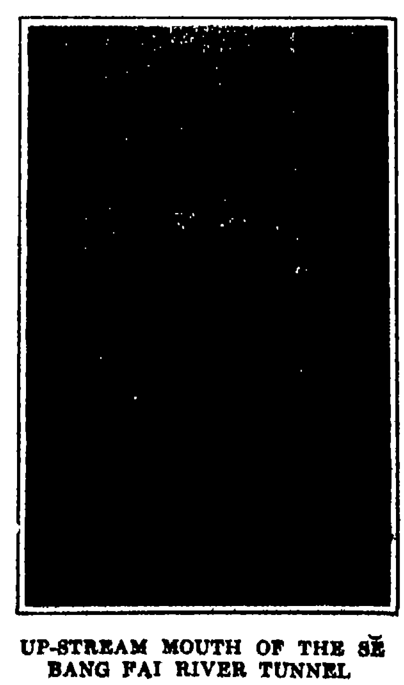
In the last 10 years the proportion of the land devoted to wheat culture has decreased from 25 to 20 per cent in Belgium, from 28 to 25¼ per cent in France, from 12 to 10 per cent in Great Britain, and has increased only in Eastern Europe. In Roumania, between 1886 to 1906 the percentage of wheat land increased from 25 to 72, and the yield per acre rose from 15 bushels in 1890 to 19 bushels in 1906 and 23 bushels in 1908. In Hungary the wheat acreage increased from 7 to 9½ millions, between 1886 and 1906. It has since fallen a little, while the yield per acre has increased.

DOWN-STREAM MOUTH OF THE HOUCI KHI HEUP RIVER TUNNEL

In France the wheat acreage decreased slightly between 1884 and 1908, but the yield per acre has risen in the last five years from 17.8 bushels to 20.2 bushels, more than compensating the reduction in acreage. The problem is less acute in France than in some other countries, as the population is not increasing. In Germany, where 4.7 million acres are planted with wheat, the yield per acre increased from 20.3 bushels in 1889 to 27.9 bushels in 1903, and has since risen apparently to 30 bushels, although this last increase may be partly due to a change in the statistical method.

In a recent issue of *Ueber Land und Meer*, Dr. Ernest Schultze quotes these statistics from Craigie's address and goes on to say that Western Europe would feel the pangs of hunger if the importations of grain from non-European countries were cut off. Furthermore, although the wheat production of the United States has increased enormously in the last thirty years, the population, and consequently, the consumption of wheat, have increased still more, so that a smaller part of the crop is available for export. In recent years Canada has become an important factor in wheat production. Contrary to expectation, the climate of the Canadian West has proved especially well adapted to the cultivation of wheat and the virgin soil of the vast prairies yields very large crops. But even these prairies are not unlimited and their fertility will soon be exhausted if the destructive American methods of cultivation are followed.

The United States and Canada, however, are not the only countries capable of producing wheat. They have already found a formidable competitor in Argentina, of whose vast area 12 million acres were planted, chiefly with wheat, in 1908. Argentina possesses 158 million acres suitable for grain production, 16 times the area now utilized. There are other countries which are



UP-STREAM MOUTH OF THE SĔ BANG FAI RIVER TUNNEL

capable of producing large quantities of grain. The wheat fields of Australia already comprise 6 million acres and the average annual exports, from 1902 to 1907, amounted to 36 million bushels. Siberia, whose climate, like that of Canada, was long misunderstood, is entering the light of grain producing lands. The production of grain can be greatly increased in Asia Minor, Mesopotamia, Sicily, Spain, North Africa and many other

regions, which in ancient times were called the granaries of Europe. Even Russia is far from being completely under cultivation. Immense quantities of grain can be produced in Manchuria, in India (with irrigation), on the table lands of Central Africa, and elsewhere. All of these lands, even if they yield only 12.7 bushels per acre, which is Sir William Crookes' estimate for the present wheat fields of the world, will supply food for a vastly larger population than the world now contains.

But the question of a possible shortage of wheat occurring within a comparatively short time cannot be dismissed so easily. Two years ago Prof Silvanus Thompson predicted that this shortage would be felt in 1921, ten years hence. His prediction was based on the following considerations: The present wheat fields of the world comprise 240,000,000 acres and produce 3,000,000,000 bushels annually. The annual consumption of wheat is equivalent to 4.5 bushels per capita of the wheat-eating population. Hence the average wheat crop is sufficient for 660,000,000 persons. The wheat-eating population, including the white race and a few fragments of other races, already numbers 585,000,000, and Prof Crookes has estimated that in 1921 it will have increased to 671,000,000, 11,000,000 more than the present crop can supply. In 1941 the white race will have increased to 819,000,000.

Thompson, however, overlooked the fact that the yield per acre can be increased, and that it has been increased in many regions, as the population has became denser and land more valuable. In the nineteenth century the area of the wheat fields of Germany was doubled and the yield per acre increased seventy per cent, so that the annual wheat production at the end of the century was nearly three and one half times what it was at the beginning. The increase in the yield per acre between 1899 and 1903, already mentioned shows that the maximum crop has not yet been attained. The improvement has been brought about by more rational methods of cultivation, selection of seed, increased use of fertilisers and the introduction of machinery, and still better results will yet be obtained.

It is certain then that the world's wheat crop can be greatly increased, and it is equally certain that the increase will be produced almost automatically as the value of land rises. This process, which was strikingly illustrated in the nineteenth century, is now taking place in the United States beginning in the east and gradually progressing westward. The American farmer is being compelled to cultivate a few acres well, instead of cultivating many acres poorly. The process will be repeated later in Argentina, Siberia, and other wheat-producing countries.

No wheat famine therefore, is likely to occur within the next few decades but no man can predict the conditions that may prevail at the end of the twentieth century.

A New Wireless Transmitter

The Lorenz System Briefly Described

THE Lorenz company has constructed a new direct current wireless transmitter the description of which will be made more intelligible by a recapitulation of what has already been done in its special field. The review and description are condensed from an article by Dr G Eichhorn, in the *Illustrite Zeitung*.

In 1906, undamped or sustained electric oscillations, produced by Poulsen's arc device, were first employed in wireless telegraphy. A receiver with minimum damping then became a desideratum and the Poulsen Pedersen "tickler" was found to give a remarkable and previously unattained facility in tuning and freedom from disturbance. Then came from America the method of increasing the sparks of the ordinary spark transmitter to such an extent that they throw the telephone membrane of the receiver into regular vibration and produce a musical sound which can be clearly distinguished from the effect of atmospheric disturbances in many cases and even from other wireless signals in favorable conditions. This idea was taken up by Gesellschaft fuer drahtlose Telegraphie. Poulsen had already devised a method of dividing his undamped oscillations into equidistant groups, which produce a very clear and easily varied and regulated tone in the receiver. This method has hitherto been employed for short distances only owing to the want of an interrupter suitable for use with very strong currents.

The same advantages are possessed by a method of

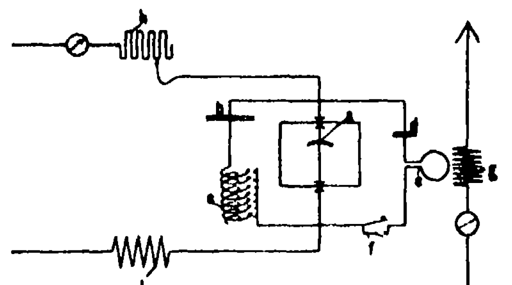


FIG 1.—A NEW WIRELESS TRANSMITTER

producing the oscillations by causing two oscillating currents, each including a luminous arc generator and slightly out of tune with each other to act upon a single antenna circuit. Oscillations produced in this way also evoke very clear and distinct tones, the pitch of which can be conveniently regulated, but only at comparatively short distances.

Two expedients have been tried for the purpose of increasing the range. In one system the arc circuit is traversed by a direct current and also by an alternating current, which periodically influences the oscillations produced by the arc. In the second system the arc is replaced by a short spark gap and the direct current is reinforced by an alternating current, furnished preferably by a Duddel oscillatory circuit, by modifying which the pitch of the sound produced can easily be varied. This system is especially well adapted for portable stations. The arrangement of the transmitting apparatus is shown in Fig 1. The spark gap *a* is formed by two electrodes of nearly spherical curvature, one convex, the other concave, the distance between which can be varied. An atmosphere containing hydrogen can be maintained between the electrodes by letting fall between them, by means of an automatic dropper, drops of alcohol, which are instantly volatilised. The Duddel circuit contains a large condenser *b* and an inductance coil *c* having a core composed of strips of thin sheet iron. This coil is divided into a number of sections, which can be opened or closed separately for the purpose of varying the self-induction of the coil. Connected in parallel with the spark-gap and the Duddel circuits is a third, called the impulse circuit, containing a small condenser *d*, a key *f*, and a few turns of wire *e*, which act by induction on the coil *g* of the antenna circuit. The discharge through the spark-gap is regulated by the variable resistance *h* and the adjustable choking coil *i*. This discharge is triple, being composed of the direct current from the dynamo or battery, the low frequency alternating current of the Duddel circuit and the high frequency current of the impulse circuit. The first and second components combine to form an alternating current which produces periodical variations in the resistance of the spark gap. When this resistance is high a series of high frequency unidirectional discharges from the antenna is produced but when the resistance of the spark gap is low and the current through it is a

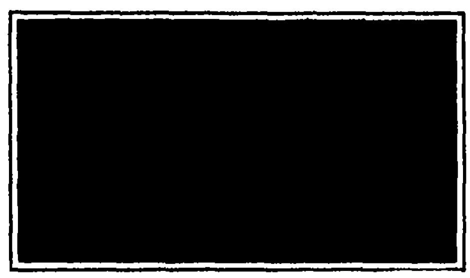

FIG 2.—GROUPS OF PARTIAL SPARK DISCHARGES

maximum the antenna circuit remains unaffected. The effect of the introduction of the Duddel circuit, therefore, is to interrupt periodically the flow of high frequency discharges which would be emitted by the antenna and thus produce in the receiving telephone at the distant station a continuous tone having the pitch of the Duddel circuit.

The apparatus is very light and its operation is exceedingly simple. By manipulating the contacts of the sections of the inductance coil *c* and leaving the key *f* closed, various tones can be produced and trumpet call signals and even melodies can be transmitted. Morse signals can be transmitted in any of the possible tones, by manipulating the key *f*. The voltage employed for the spark gap does not require nice adjustment, the inductive connection between the impulse circuit and the antenna admits of wide variation and these two circuits need not be accurately in tune with each other.

Four groups of high frequency discharges through the spark gap, alternating with intervals of darkness, are illustrated in Fig 2 while Fig 3 shows the last four discharges of a group and Fig 4 the first discharge of the succeeding group.

Toncan Metal

By F M ENGLISH

THE development of Toncan metal was undertaken to meet the demand for a black or galvanized sheet which would be moderate in price and have the highest corrosion resisting qualities for use in roofing, siding, eaves trough, conductor pipe, and for all other building purposes into which such sheets enter.

In undertaking the development of a sheet of this character, the manufacturers have been guided throughout by

FIG 3.—THE LAST DISCHARGES OF A GROUP

the old-time iron master and by adapting old-time principles to modern methods as far as possible.

The problem of the iron master in making the quality of sheet which he did was infinitely simple as compared to the one facing the modern iron or steel maker, who undertakes to reproduce sheets having the corrosion resisting qualities of the old-time goods and which also combine all the other qualities requisite in a sheet which must meet modern requirements.

Had we to-day the same raw materials, the same workmen the same furnaces and exactly the same conditions, sheets could be made in all respects equal to any that have ever been made but could the manufacturer with such facilities begin to supply the present enormous demand and could he reproduce sheets at a price which would permit of their use in the vast variety of ways in which sheets are now being utilized?

To meet the present day demand for sheets—to enable the mills to keep pace with the ever increasing consumption because of the infinite variety of ways in which sheets are being employed—the slow limited methods and processes of the past cannot be employed or reinstated.

The problem now confronting the sheet manufacturer is how to make sheets having the old time corrosion resisting qualities together with the necessary working qualities and at a price which will not curtail their use. And it is no easy one. In other words the sheet manufacturer must now make two dozen blades of grass grow" where one grew formerly not at the same price and of the same quality but at a lesser price and of better quality and with higher labor inferior raw materials, and to withstand much more exacting conditions.

The conditions to which sheets are now subjected as compared with earlier times are also entirely different—

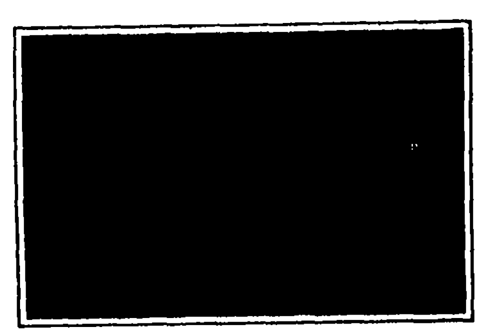

FIG 4.—THE FIRST DISCHARGE OF A GROUP

the demands and requirements of trade are far more exacting. The sheet of to-day to meet modern exactions, must have not only the highest corrosion resisting qualities, but they must have working qualities also, and be able to withstand strains and stresses in shaping, forming and handling never dreamed of in the past, to say nothing of the vastly changed atmospheric demands to which they are now subjected. The sheets of the present time, to meet all requisitions must be better than the old time ones and not only better but cheaper.

In placing this new rust resisting metal on the market as a material in which are combined all the qualifications necessary in the modern sheet, whether galvanized or black, it is classed as a metal rather than as an iron or steel, because while it has corrosion resisting qualities equal to the old time iron it also combined many characteristics of the highest grade mild open hearth steel, making it the ideal material with which to meet all requirements of the latest sheet metal practice, in that it will not only withstand corrosion but also the strains and stresses of shaping and forming without fracturing.

It is an undisputed fact that the corrosion-resisting qualities of the early sheets were due entirely to their uniformity or homogeneity which was made possible by the proper selection of raw materials through the principle involved in their handling and through the care and attention with which the iron was made. Plenty of time was given with the raw materials while in the furnace, to eliminate any excess foreign impurities present and to properly combine those remaining and also by handling the iron after it came from the furnace in such a manner that segregation did not take place during the reheating or working up processes.

Through modern research and investigation we know that corrosion is caused by the carbon sulphur phosphorus and manganese becoming segregated, during the process of manufacture this theory having been fully demonstrated both in the laboratory and under actual

working conditions the corrosive action taking place in the following manner:

When the impurities carbon sulphur phosphorus and manganese become segregated in iron or steel that is when they are not equally and evenly distributed throughout the metal occurring in small spots or areas, an electrical current will be set up between these segregated points whenever the sheet in which they are present, becomes covered with a film of moisture from the atmosphere Due to differences in composition some of these points of segregation become positive others negative which when connected by the film of moisture set up numerous electrical batteries of greater or lesser energy according to the extent of the segregation so that there are limitless numbers of small electrical batteries continually at work throughout the sheet It is a well known fact that a current of electricity cannot be generated in a battery without destruction or dissolution taking place at the positive pole so that in any sheet iron or steel in which segregation has taken place and the surface of which through exposure to the atmosphere has become covered with a film of moisture, there are numerous small electrical batteries at work at the positive poles of which the iron or steel is being destroyed resulting in the form of corrosion known as pitting a form with which manufacturers are all only too well acquainted The more marked or strongly defined is the segregation the stronger will be the electrical action; consequently the more rapid will be the destruction of the metal or sheet On the other hand the less well-defined the segregation the weaker or milder will be the electrical action and consequently the life of the sheet will be longer Again in a well made sheet of iron or steel in which the impurities have been properly incorporated and segregation reduced to a minimum the electrical action will be so slight that pitting will not take place but instead an even coating of rust will be formed over the entire surface of the sheet in such a way that the rust will itself become to a great extent a protective coating greatly retarding the process of decomposition or rusting It was for this reason that the old time iron sheets withstood so phenomenally the ravages of corrosion It was not because they did not rust that caused them to last but the way in which they did rust that made them so long lived

No iron or steel has ever been made or can ever be made that will not rust in moist air because it is the nature of all products made from iron ore to rust and in time return to the natural state from which they originally came. But the way in which the rusting takes place can be controlled, thus making the sheet long lived, durable and the most ideal metal for roofing, siding, eaves trough conductor pipe and other similar purposes

It has generally been supposed that steel corrodes faster than iron, also that pitting is confined entirely to steel, but this is by no means the case. Both iron and steel pit and corrode, and badly made iron, of which we are getting a great deal to-day lasts no better than badly made steel The opposite of which is also true, namely, that properly made steel will withstand corrosion and pitting equally as well as iron, besides having far superior working qualities

There may possibly be some question as to how electrolysis takes place in causing corrosion as regards the exact chemical reactions but that electrolysis actually does take place, and that it is the true cause of corrosion cannot be successfully disputed The fact that electrolysis does occur is proven conclusively by the ferroxyl test exhibits of which all manufacturers have examined The object of this test is not to show the comparative lasting qualities of two or more pieces of metal, but only to prove the theory of electrolysis by practical demonstration

The explanation of the test is this: At the poles of all electrical batteries two elements are always found to be present namely hydrogen ions and hydroxyl ions The hydrogen ions cluster around and indicate the positive pole The hydroxyl ions in the same manner indicate the negative pole The ferroxyl testing reagent is composed of certain indicators, the reactions of which when brought into contact with these two elements, have been known for years Ferroxyl is a weak acid, and is of such a nature that when brought in contact with hydroxyl ions it at once produces a pink color while potassium ferricyanide when hydrogen ions are present, causing iron to be dissolved or corroded produces a blue reaction Both of these chemicals are present in the gelatine mixture in which are embedded the samples which you have examined the blue color indicating the positive poles where destruction or corrosion is taking place, the pink color indicating the negative poles No piece of iron or steel has ever been found which, when subjected to this test will not sooner or later develop the pink and blue reaction which all have witnessed

The point involved then in the manufacture of iron or steel which is to resist corrosion is to so combine and work up the raw materials that these electrical currents, which cause corrosion, will be of the mildest form and whose action is not concentrated or fixed through excessive segregation.

Of the many subjects which are of interest to the sheet metal worker and the user of sheets there is none of such vital importance as the subject of corrosion, and what affects the sheet manufacturer, so that the cause and cure of corrosion is of common interest to both

If the sheet metal business is to grow, expand and assume the position in the world of business which it should, it is absolutely necessary that the sheet metal workers strive in every way to use only such sheets as will stand up for at least a reasonable length of time and to avoid wherever possible the use of goods that will prove disastrous to his business and his reputation Manufacturers of sheets have long recognized this fact, and for a considerable time a company at Canton, Ohio, has been carrying on a series of exhaustive tests and experiments to produce a material which would be reasonable in price and meet all requirements—both as regards corrosion resisting qualities and working qualities—thus placing within reach of every worker of sheets a material with which to combat and overcome the ever increasing prejudice against sheet metal for building purposes, a prejudice which has, of late years, been steadily increasing, due to the unsatisfactory lasting qualities of a large majority of the materials which are now on the market.

The result of these efforts is rust resisting metal, a material which combines the essential qualities of high corrosion resistance ductility, and moderate cost. A long series of acid salt and creosote tests have been carried on in addition to carefully noting results of exposure to actual every-day working conditions.

With the necessarily incomplete outline of the qualities and characteristics of this rust resisting metal, and of the subject of the corrosion of iron and steel, we leave the subject, hoping it will receive from the sheet metal worker the further consideration which is its due. The subject is certainly one of vital importance to every sheet metal worker because the development and growth of the industry will be determined largely by the degree in which corrosion is manifested in the materials adopted and used The employment of highly corrosive material will retard and lessen the demand for the sheet metal work while the use of better and more lasting material will stimulate and encourage the demand

The Aggregation of Power Systems*

Economic Limitations of the Big Power Station

By Robert A Philip

Limitations on the distance to which power can be transmitted electrically have been investigated from time to time In this paper it is the purpose to point out that the limiting distance of transmission is not the limit of economical interconnection and that there is probably no such limit It is also the purpose to outline certain principles of electric transmission which indicate the line along which unlimited extension of electric net works may proceed

Electric power promises to become the universal power of the future It is not a substitute for steam power or water power It competes with no prime mover Electric power is essentially a secondary power Prime movers produce useful but crude mechanical power from the rough irregular forces of nature Mechanical power transformed and refined in the electric generator, becomes electric power the highest known form The highest form because it can be changed to other forms heat light motive power chemical action with unparalleled directness and simplicity It is the uniform method of applying any kind of power from any source to any work To other powers it stands as a common medium of exchange Prime power is like property electric power like money

The electric motor consumes electric power produced by an electric generator driven by a prime mover When an electric motor is substituted for a steam engine the load is merely transferred from one prime mover to another There is a loss of power in the electric generator a loss in the electric transmission line and a loss in the electric motor In spite of these losses electric transmission and distribution of power is commercially successful because of economy flexibility and cleanliness

The motor is economical merely because the prime mover on which it ultimately depends is still more economical; that is electric power is an advantageous means of producing competition between different prime movers and thereby displacing those that are wasteful Every circumstance unfavorable for economical power generation can be found in varying degrees among isolated plants while central electric generating plants may take advantage of every practicable economy Certain highly important differences favorable to centralized prime movers are greater size greater diversity factor, greater load factor convenient location for fuel and water and cheap land Of these some are automatically cumulative As the plant grows its economy increases, and as the economy increases it surpasses that of more and larger isolated plants, displaces them and thereby grows some more Furthermore, electric power is not limited to bringing a large prime mover into competition with a small prime mover of the same kind; it goes farther, taking for its source any other kind of prime mover which may be more economical The economy of electric power is essentially progressive and is only limited by that of the best prime mover of any size any kind anywhere

Power is used to produce results The requirements for economical production and economical application of power are antagonistic Concentration and continuity are essentials for favorable production while subdivision and controllability best adapt it to its uses Electric power reconciles these diverse requirements While concentrated at the continuously running generator it is subdivided at the intermittently running motors

Essentially a secondary power it consumes no raw material and emits no waste material No water or fuel goes in no ashes water or gases come out Increased human activity and efficiency require and depend on increased power per capita per square mile per cubic yard Contamination of the air by prime movers sets an artificial limitation to beneficial concentration Electric power removes the limitations and opens up new possibilities The modern city subway can be operated by electricity and by that alone

The principle underlying the success of electric power is that of uniformity Incidentally to be uniform, the method must be indirect The same principle underlies the use of money Property may be exchanged directly by barter but the uniform method of indirect exchange by purchase and sale is superior In each case the intermediate medium of exchange gives the flexibility necessary for equalising production and consumption on a large scale The public service corporations which distribute power have a function analogous to a banking system They constitute clearing houses for balancing the individual increases and decreases of power requirements of a community as a whole and provide a centralized reserve for meeting promptly any total net increase

The power plant which does not use electric power stands alone In the continual readjustment of industry there are shifting deficiencies and surpluses of power which cannot be economically met by increasing, decreasing and moving local prime mover power plants In the aggregate, the disproportion of the isolated prime movers to their loads must be enormous. This leads to the conclusion that there is a great collateral advantage in using electric power, wherever practicable as an intermediate step between the prime mover and the work, thereby providing the necessary means of immediately and without further expense participating in the advantages of uniting resources with the rest of the community whenever emergency, convenience or economy require it.

The success of electric power distribution and transmission has been due largely to two specific applications of the underlying principle of uniformity First, that it is cheaper to generate power by steam in one large plant than in numerous little plants. Second, that steam power may be economically superseded by otherwise impracticable water powers These two applications have built up two classes of transmission systems those from central team plants originating at the large centers of population and radiating into the country where they supply current for railways light and power in outlying towns and villages; those from water powers starting from the mountains and converging toward the cities These applications alone though stimulated by increased consumption and higher price of fuel, may extend the economical radius of transmission, but not indefinitely

On the other hand if there is no increase in the economical radius, nevertheless the continued development which may be reasonably expected along present lines will in time cover the country with high tension distribution and transmission lines These lines will form short contiguous but independent transmission systems, each one having a specific function of distribution or transmission which pays for the interest on the investment, the repairs and maintenance and the cost of power used up in core loss and other friction or leakage necessary for keeping the system alive While each line is useful and necessary, every line is subject to periods when it is idle In other words its load factor is low During off peak hours, power can be transmitted subject to no charge for interest, repairs or maintenance and free of deduction for the constant losses of the system Devoid of these encumbrances, the usual limitations to the distance to which power may be transmitted do not hold.

This opens the way to a broader application of the principle of uniformity The differences in economy between large and small steam plants and between steam and water power plants are not the ultimate limitation to transmission Were the limitations reached in these two directions there remains a vast field of economy in applying the principle in other directions

Diversity factor alone contains almost inconceivable possibilities Whenever there is intermittent work diversity factor may be expected In so far as it is unnecessary to do two different things simultaneously it should be unnecessary to duplicate the power supply Since the point of application of electric power may be instantly transferred from place to place, only a half (or other fraction, as the case may be) of the prime power is required in a central plant which would be needed in two or more separate local plants This fraction is the diversity factor It has already done much to enhance the advantage of the large plant over the small one, but the large plants in turn are governed by local conditions and, like the isolated plants they supplant, they have important diversity factors among their loads. Thus the conditions determining the hour of peak vary considerably in different cities, with the industries and customs of the inhabitants, with local weather conditions, with

*American Institute of Electrical Engineers

the altitude, latitude and longitude; the artificial convention of standard time makes an hour's difference in time of starting work in nearby cities and over greater distances the natural difference in time makes greater differences.

Water powers have a peculiar species of diversity factor of production due to non-coincidence of deficiencies. While there are dry years in which all water powers may suffer deficiency, the idea of coincident deficiencies is largely due to insufficient and inaccurate records. From the nature of the case the rains, snow fall, freezing and thawing must vary widely according to the location and exposure of the watersheds. There will be some diversity between the flow of any two streams though they be adjoining, a greater diversity between those on opposite sides of a divide and more between those on different mountain groups. A large river which runs dry for short periods for lack of storage and a large reservoir on a small stream are each defective for power supply, but together they may be mutually supplementary. By combination the bulk of the power may be derived from rivers on one watershed the reserve storage from those on another.

More remotely the general extension of transmission may open up possibilities of developing the intermittent powers of nature which, variable and unreliable in any one locality when taken over a large area, or in connection with each other or with existing developments, may be found to be uniform and reliable. Thus the tides occur at different hours and at different points. Variable powers such as the wind have appeared impracticable largely because they have never been studied adequately and if developed locally require a prohibitive expense for regulating equalizing and storage. Comprehensively developed as an auxiliary to an established system which could use the power as available, the cost of power from these sources would be far less than has been heretofore supposed.

Transmission lines are the highways of power. Having made power portable and universally applicable by reducing it to the electric form it is inconceivable that the highways over which it travels will not be vastly more useful if interconnected.

More definitely there is the present problem of existing transmission systems growing beyond the bounds for which they have been designed by the annexation of adjoining independent systems as one by one the collateral advantages pass into the domain of accepted fact.

To design a transmission line to transmit power from a water power plant to a city is a definite problem. To interconnect two such lines to accomplish some auxiliary purposes not in the original design is quite a different problem. The interconnection of two transmission systems is like combining two railroads, first, there must be a physical connection then unified operation. As the gages of the railroads must be reconciled so the frequencies, phases and voltages must be adapted by reducing to a common standard or the power must be converted at the junction points. Then the flow of power in the network must be controlled so that, within the limitations of the wires provided power may be transferred at will from points of surplus to those of deficiency. This problem of interconnection differs from that of transmission in introducing as an element the idea of reversible transmission, that is, either end of the line may be generating or receiving end.

The interconnection of two systems forecasts future connection with a third and fourth. Such extension carried on indefinitely leads to the conception of a single vast system which may be built up in the future. Electric power is successful because it is the one uniform method of equalizing supply and demand. Every extension and interconnection broadens the field in which it can act and should increase its success. Continued indefinite extension is desirable and inevitable if possible.

As electric power is like a common denominator to which all other power is reducible so alternating current is the common form to which electric power itself must be reduced to become universally available. Direct current is useful and necessary but its function for the present at least, is that of a form auxiliary to or derived from alternating current and limited in the distance which it can travel to a single locality. Alternating current combines a suitability to the high pressure necessary for transmitting power in bulk long distances with a simplicity of division and subdivision both of power and pressure which is necessary for the ultimate distribution. Furthermore, the alternating current system has unique qualities which especially suit it for reversible operation and thereby adapt it for indefinite extension.

Electric currents are commonly regarded as flowing from points of higher potential to those of lower potential. With direct currents the potential of the generating end of the line must be higher than that of the receiving end directly in proportion to the power delivered in order to overcome the line resistance. With alternating currents delivering the same power over the same line at the same voltage and at unity power factor, the potential of the generating end must be still higher as the reactance as well as the resistance of the line must be overcome even if the power is delivered at unity power factor, which is usually regarded as the most favorable case for alternating transmission. If the power is delivered to an inductive load the power factor will be lower than unity and the potential of the generating end must be higher yet in order to force the magnetizing current over the line in addition to the working current.

To provide for the variation of drop of potential in a transmission line at varying loads numerous devices are used. The generator voltage may be varied through adjustment of the field rheostat or by compounding; the ratio of step-up and step-down transformers may be made different so that the generator voltage will be the same as the receiver voltage at full load instead of at no load, as would be the case if the transformers had the same ratio; or separate boosting transformers may be used to the same end; a regulating dial connected to taps to the transformer windings may be used to vary their ratio, or a regulator consisting of a separate transformer of variable ratio may be used for the same purpose.

While in ordinary alternating-current transmission supplying only lights and induction motors the potential at the generating end is necessarily higher than at the receiving end, in a transmission line supplying a synchronous motor taking a leading current the condition may be reversed and the potential may be higher at the receiving end than at the generating end so that the current flows from a point of lower to one of higher potential.

While leading currents may cause the potential at the receiving end to be higher than at the generating end they do not do so necessarily. With a large amount of leading current the potential may be higher at the receiving end, but with a small amount it may be lower and with an intermediate amount it may be the same at the two ends and may be maintained the same even if the load varies by a corresponding variation in the amount of leading current.

Power may therefore be transmitted over a line by alternating currents without change of potential and a system may be built up by adding other lines until a network is formed uniting many power houses and many substations. In such a system the potential may be the same at the bus bars of every power house and every substation and yet power may be transferred at will through the network in any direction. Since the potential at the edges of such a network is the same as at the center it is evident that the system is capable of indefinitely great extension. While the power is transmitted without loss of potential there is a loss of energy equal to the square of the current multiplied by the resistance as usual. The possibility of extension is not for the transmission of power in bulk for indefinitely great distances but rather for the extension of a network containing points of generation at intervals the load being equalized on the points of generation by means of the network which permits of power being transmitted to or from any point in any direction for distances as great as considerations of emergency or economy may indicate from time to time.

In view of the customary drop of potential from the generating to the receiving end of the line transmission without this drop may at first seem to be an abnormal and unstable condition but this is not the case.

Suppose two identical machines connected by a line one run as an alternator and the other as a synchronous motor. If the resistances and reactances of the armatures are so small as to be negligible and if the strengths of the fields are so great compared to that of the armatures that the effect of armature reaction is negligible then this combination will automatically transmit the power with constant potential at each end of the line independent of load and of line impedance. If the armatures of the machines have appreciable resistance or reactance there will be a drop of potential from no load to full load, but it should be noted that the drop results from the resistances and reactances in the machines, not those in the line. It is therefore only necessary to improve the regulation of the machines themselves to attain a natural constant potential transmission system.

To operate a synchronous motor on the constant potential system we should therefore adjust its field not according to a power factor meter but according to a voltmeter on the line as it is normal line voltage not unity power factor on the motor which is desirable. The condition previously assumed that the synchronous motor is a machine which is a duplicate of the generator is not essential also any other kind of load may at the same time be supplied by the same line. Where both synchronous and induction motors are operated from the same line the voltmeter method of adjustment has the advantage of simplicity in that the proper adjustment of the field of the synchronous motor for overcoming the lagging currents of the induction motors is obtained thereby although the currents taken by the induction motors are unknown to the one making the field adjustment. Where synchronous motors are used on lighting systems the advantage of operating them on the constant potential system is obvious for if correctly operated in this manner the regulation of the system which is of prime importance becomes perfect.

Taking again the case of the two-machine transmission just considered. Suppose a mark made on some point of the rotor of the generator and a similar mark at the corresponding point of the rotor of the motor. At no load the marks will reach the top of the circles in which they revolve at the same time indicating that the voltage of the motor is in phase with that of the generator; as the load comes on the mark on the motor will fall behind that on the generator reaching the top position a little later indicating that the voltage of the motor is falling behind that of the generator. This illustrates the principle that in constant potential transmission current flows and power is transmitted from points of advanced to those of retarded phase. In other words, the potential of the receiving end must drop behind that of the generating end in phase instead of below it in magnitude.

In a direct-current transmission with constant generator potential the amount of power transmitted increases with increased drop of potential up to a certain maximum and then decreases again so with constant potential alternating transmission the amount of power increases with increased retardation of potential phase up to a maximum and then decreases again. In each of these cases the range from no load to the maximum load is the range of stable operation, beyond the maximum is a range of unstable operation. In each case too, the maximum power which may be transmitted depends on the constants of the line. The greater the resistance the less power that may be transmitted by either direct or alternating currents. The analogous assumption that the greater the line reactance the less the power that may be transmitted by alternating current is incorrect. With no line reactance no power could be transmitted at constant potential but as all lines have some reactance this case would never actually occur. Up to a certain limit the greater the line reactance the greater the maximum amount of power which may be transmitted. For every transmission line there is therefore a range of stable operation for constant potential transmission.

The utility of a system of transmission depends partly on the ease with which its operation can be foretold by calculation. On this basis the constant potential system is at a great advantage for its characteristics can be shown in a simple diagram constructed from constants which are readily calculated and have an easily understood physical meaning.

The constant potential alternating system is on a par with direct current as to the amount of power and as to the efficiency of transmission over a line of given resistance and voltage.

A comparatively high line reactance is a favorable feature both as regards amount and efficiency of power transmission and therefore a frequency of sixty cycles per second may be better than one of twenty five cycles for power transmission.

Reactance makes a line opaque to short circuits, but wattless power introduced at the receiving end makes it transparent to the flow of useful power therefore the power at short circuit may be less than at full load.

A short circuit may be a local matter not interrupting the service of the system as a whole not affecting the voltage except for a limited radius and not draining any extraordinary amount of power from the system.

Switches of limited capacity may be safely used on systems of unlimited power.

Blocks of power too great to be safely controlled may be subdivided by artificial lines instead of being entirely separated.

There are no limitations to amount of phase difference therefore none to unlimited extension at constant potential but in distant parts of a large system the difference may be so great that one machine may be one or more complete cycles (or even revolutions) behind another.

In interconnecting different branches of a large system the actual as well as the apparent phase difference must be considered therefore the readings of any ordinary synchronizing device may fail to indicate the true phase relation.

Constant potential transmission requires controllable leading currents synchronous motors are the practical source of such currents therefore the first step in establishing such a system is to have as large a part of the receiving equipment as possible composed of synchronous motors to have these motors designed for carrying full load with leading currents of say 80 per cent power factor and to have their voltage controlled by non compounded voltage regulators.

Rotary converters are synchronous motors but as ordinarily constructed are poorly adapted for operation with leading currents.

The electrostatic capacity of transmission lines furnishes leading currents which are not directly controllable and are therefore not the equivalent of those from synchronous motors.

Synchronous motors can take lagging as well as leading currents, but the lagging currents taken differ from those of induction motors in being controllable.

The leading currents of line capacity and the lagging currents of induction motors subtract and add respectively certain amounts to the available leading currents to be furnished by the synchronous motors, that is they do not affect the range of control required but rather shift the mean position of this range toward lagging or leading respectively.

To summarize the principles here outlined. First is that of the solidarity of the power market as a whole next is that of the place of electric power in this market which, not itself a prime power yet is the common medium of exchange for all prime power. From this follows naturally the indefinite extension and interconnection of transmission lines, the highways of power. Underlying all these is the requirement that electric power though poured in unlimited amounts into a system of indefinitely great extent must be as mobile as the trains on the country's railroad network must be universally uniform in quality must never be totally interrupted and though in amount unlimitedly great must not be uncontrollable. To meet these requirements electric power must take the alternating current form and should be transmitted on the constant potential system. Finally this system is one using high line reactance made transparent by leading wattless currents and transmitting power by displacing the phase of the voltage instead of varying its amount.

The governor of the Ubangui and Tchad regions of central Africa has lately issued regulations prohibiting the hunting of the elephant with fire arms and the setting of traps for this animal. The rules also forbid the killing of female elephants and of young immature specimens, whose tusks weigh less than 11 pounds. The elephant in Africa is not domesticated as it is in Asia, and this leads to the indiscriminate killing of the animals in order to secure the spoils. However, under such conditions there is danger that the elephant will become exterminated before long. An international conference has been held upon this question and a set of measures have been framed and recommended for promulgation.

A Gasoline Tractor of 100 Horse-power Capacity

A Mechanical Horse for the Farm

By Frank C Perkins

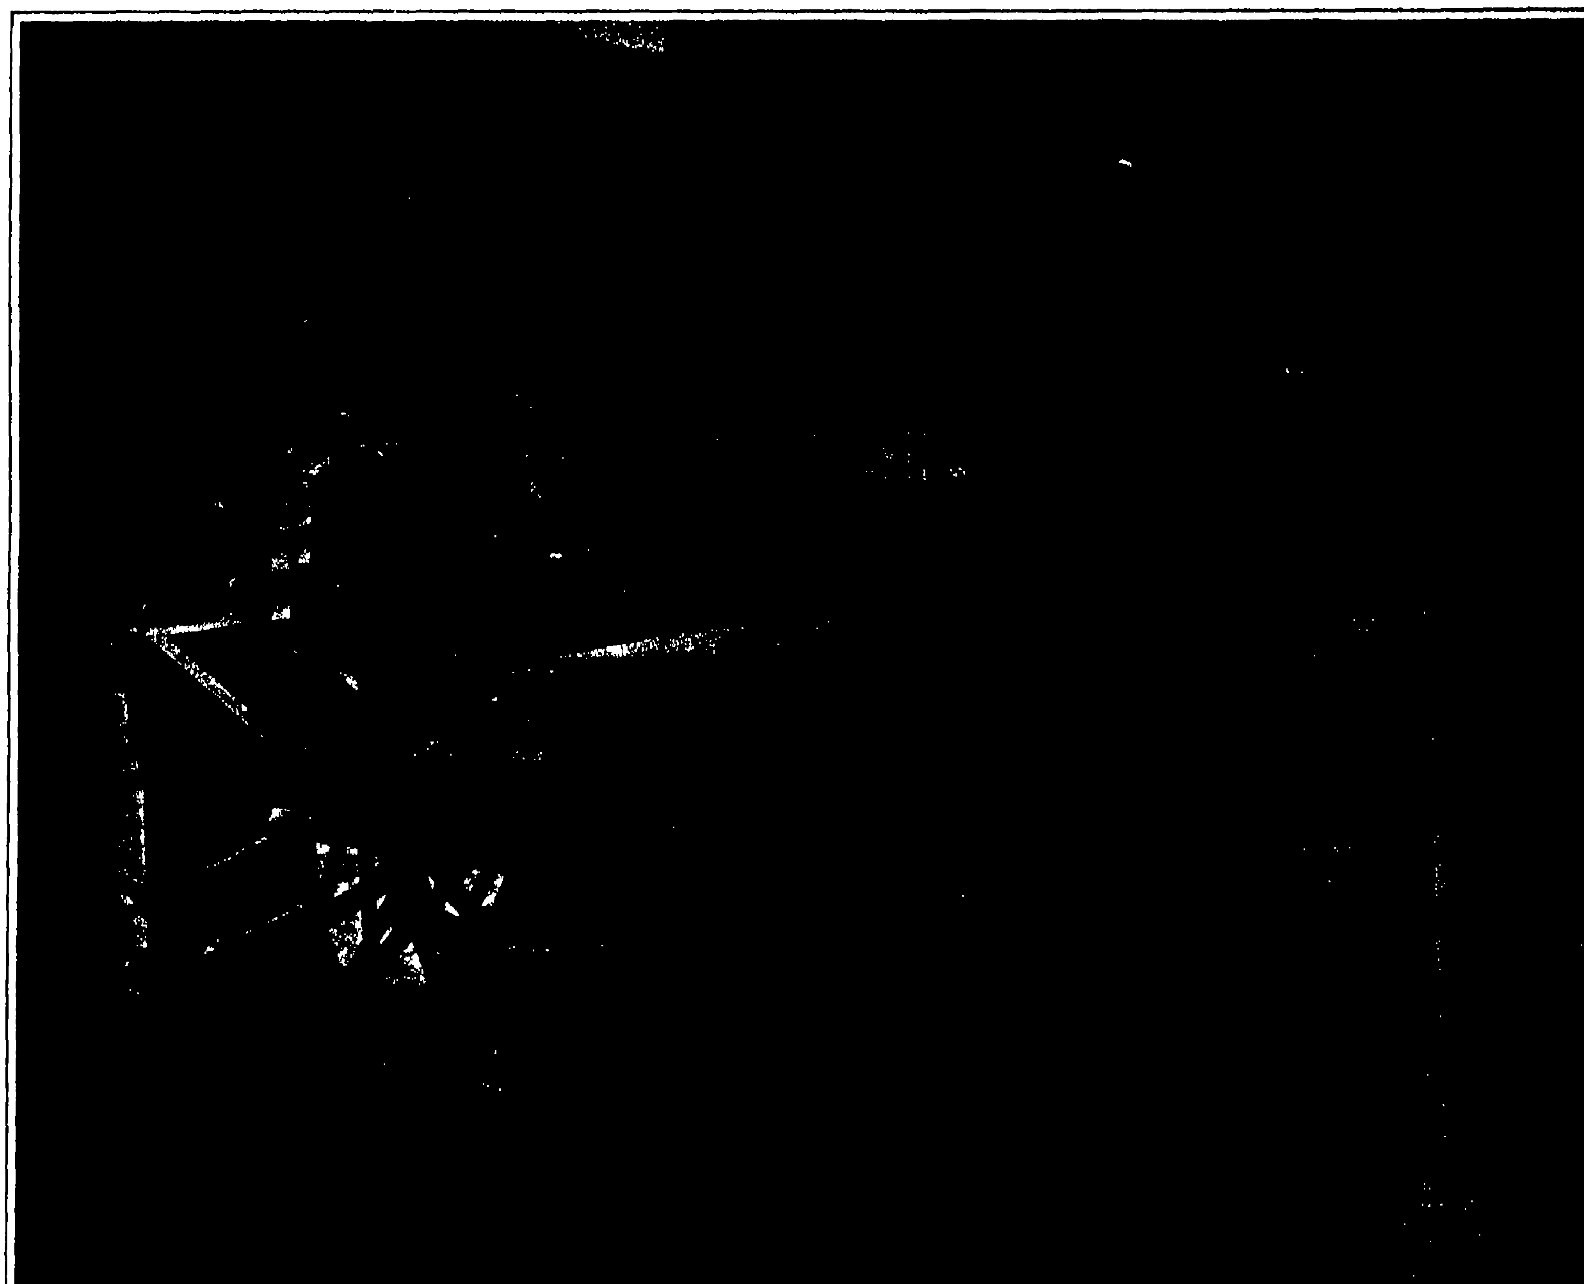
THE accompanying illustration shows the construction of a novel gasoline or oil tractor designed at Racine, Wis for use on the farm in plowing hauling and threshing or for driving saw mills shingle mills pumping machinery or stone crushers This gasoline tractor is equipped with a four cylinder motor of the four cycle type developing from 81 to 100 horse power

The piston speed is 750 feet per minute and the four cylinder engine develops 81 horse power at 450 revolutions per minute the cylinders having a diameter of 9 inches and a stroke of 10 inches The fuel consumption averages one pint per horse power per hour The crank shafts have five bearings lined with babbit, the shafts being forged of solid steel The connecting rods are through the shafting axles and boxes, which are carried by the I beams.

The design of the spring-mounting is quite an important feature in engines of considerable size On this tractor helical springs are used two in each box. The cylinders engaging the springs are cast with steel flanges at their upper ends which are riveted to the under sides of the I beams at the required position The hollow pistons which contain the springs are turned up to fit into the cylinders so as to work freely inside them. The lower end of these cylinders are forked to fit the trunnions on the axle box proper so as to allow free movement in every direction and additional springs are provided to absorb shocks when traveling over rough of the tractor so arranged that any number of plows can be attached within the range of the power of the tractor or a single draw bar may be used for hauling wagons.

Experiments with a Quartz Mercury Arc

A MERCURY arc when properly formed, can be made to rotate very rapidly This fact was brought out by Prof Dufour of Paris He uses an inverted bulb partly filled with mercury and a quartz tube is pushed up through the mercury until the end is somewhat uncovered, thus dividing the mercury into an inner and an outer zone separated by the quartz. Connecting the current to the two zones and making a vacuum, an arc is formed across the end of the tube between the two portions of



ONE HUNDRED HORSE POWER GASOLINE TRACTOR ESPECIALLY ADAPTED FOR FARM WORK

of the same material and two and one-half times the length of the stroke

The machine is self-oiling All that is necessary is to occasionally replenish the reservoir with oil a force pump does the rest The oil reservoir or splash box is made of galvanized iron and is bolted to the motor main frame being "oil tight" It can be easily removed when the entire crank shaft is exposed to view and all parts inside the crank case can be freely inspected or adjusted

The exhaust is carried by a manifold pipe directly to a very efficient muffler which completely deadens all sound without causing any back pressure The water is circulated by a powerful rotary pump and is discharged through gratings into a fan where it is effectually cooled before entering the storage tank This tank is placed on the forward part of the tractor over the front wheels

The frame is composed of I beams one on each side, with cross pieces extending between them to which they are riveted Braces are attached to the upper and lower cross pieces to prevent any twisting of the frame through the strains incident to the transmission of so much power roads The front axle is mounted on springs of the same type, and has free movement in every required direction This arrangement is neat, and works perfectly causing the machine to ride very smoothly and preventing the jarring off of nuts and the working loose of parts, so common an occurrence in engines without springs

The rear wheels are of steel, and have steel hubs. They are 6 feet in diameter by 24 inches wide The spokes are riveted to the steel hubs and to the angle iron rings inside the rims by two ¾ inch rivets at each end—put in hot by machinery

Extensions are provided to attach to the wheels for plowing on rice or cotton lands, at an extra cost, according to width The front wheels are 43 inches in diameter by 14 inches wide and are of ample strength, yet as light as it is thought safe to make them

The steering wheel is situated near the center of the length of the tractor and near the right side, so that the steersman can see the road ahead of him, and is at the same time within easy reach of the controlling levers, the clutch lever the reverse and the brake, also the carbureter switch, magneto and governors on the motor

Adjustable hitching bars are located at the rear end mercury Such arc is found to rotate at a very high speed around the end of the tube, so that it appears to the eye as a ring of light. Experiments with a revolving mirror show that the arc rotates in fact and is not continuous. He calculates the speed to be from 8,000 to 15,000 revolutions per second. This latter number is obtained when the arc is placed in a strong vertical magnetic field, by mounting the whole apparatus between the poles of an electromagnet. Here the arc changes in character and gives a brilliant light. Considered from a practical standpoint, the expenditure of current in the electromagnet does not follow the increase of light, which is an advantage.

It is reported in the *Railway Gazette* that the government of Panama have contracted with the Panama Railway Company to build a line from the city of Panama to David, the capital of the province of Chiriqui. The distance is about 274 miles, and it is expected that the route surveyed by the Intercontinental Railway Commission in 1893 will be followed. The line will traverse a rich district, and will be an important factor in the development of a large and fertile section of the republic.

A GREAT POLAR BEAR STANDING ON EDGE OF ENORMOUS ICE PAN

SO MANY of my friends have asked me how the large polar bears were captured which I brought back from my recent hunting expedition in the arctic regions and presented to the New York Zoological Society that I am tempted to gratify a desire that is perfectly natural

On Saturday, July 30th, at three o clock in the morning in one of the small bays of Ellesmereland, about the seventy-seventh parallel, we sighted a large bear on the ice, a mile or two ahead He stood on the very edge of an enormous pan of ice which extended some two miles back to the shore The lofty mountains of the mainland, furrowed with enormous glaciers, made a beautiful background, and the cold midnight sun, together with the arctic calm, completed a picture that any man would remember to his dying day

The bear stood with his long neck thrust well forward, trying to get our scent Probably he never had seen man before We headed almost straight for him, and when the ship hit the ice a hundred yards to his left, he took to the water like a duck

One of the most remarkable things about a polar bear is his cleverness in diving from a pan ice The most difficult dive for an expert swimmer to make is from something almost at a level with the water The bear makes a more beautiful dive than I have ever seen made by a human swimmer and when he glides into the water, he leaves hardly a ripple behind him They cannot stay under water very long however as we found when pursuing them with the launches

We quickly decided to take that bear alive and after cutting him off from the ice we lowered our launch and started in pursuit Although these bears are able to stay in the water for hours, they are not very fast swimmers; and we very easily overtook our quarry When we ran close up to him he turned to fight, and then we threw a rope lasso over his head took a turn on a cleat and started to tow him to the ship His struggles the hands on deck they were compelled to hold the animal very tightly to keep him from climbing into the launch Presently it seemed to me that the bear was choking, and I ordered the rope loosened at once Too late! His eyes were glassy and he was stone dead

This unfortunate experience taught me something however in the art of catching large bears, and I decided to use different tactics the next time At the same time we discovered that the cages bought from an animal dealer in New York were too small the dealer evidently thinking we intended to catch cubs whereas in reality we were expecting to capture bears weighing from 900 to 1 100 pounds The first mistake we made was in getting the rope squarely around the neck of the animal, so I decided that the next bear we roped I would leave the noose slack until we had gotten his forelegs through it when we could hoist him on board and lower him into the hold without any danger of choking him

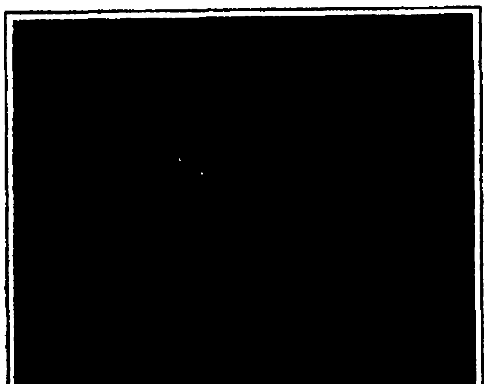
On Thursday, August 4th, we sighted a large bear that the Eskimos took to be a female but which proved to be the large male bear now in the Zoological Park swimming among the small broken pans We lowered the launch and started after him We had considerable difficulty in getting close to him, as he would gain on us very rapidly whenever he crossed over a pan which we were compelled to go around Finally however we succeeded in cutting him off by running between him and the pan for which he was making Just then a very laughable thing happened Capt Bartlett who was steering the launch was sitting on one side at the wheel When the bear saw that he was cut off from the pan he dove and we thought he would come up at the other side of the boat This, however was not in his mind and he came up directly alongside and smashed the boat a terrible blow just about a foot under Capt Bartlett Bartlett gave one wild jump across the boat not even taking time to change his sitting position and is not a very pleasant position to be in At this time the bear could very easily have gotten into the launch!

Finally however we succeeded in slacking away the rope got the engine going astern and gradually started to drag the animal into the water It was a wonderful sight to see this enormous brute with a strong rope just behind his fore shoulders He would rear on his hind legs bite at the rope and jump up and down but the good old Standard motor in the launch did not go back on us and we steadily and surely dragged him toward the edge Finally seeing that the inevitable was coming with a vicious growl he plunged into the water and started for the launch

We did not have much difficulty in keeping him out except when we were turning the launch around and getting it going ahead toward the ship half a mile distant The way he churned the water and twisted and surged was really thrilling but he had left the ice pans forever

We signalled the ship to move into open water as we needed plenty of sea room in which to handle our bear having had all the experience we wanted in the broken ice

After we had gotten some 200 or 300 yards away from the pan ice the big brute succeeded in getting out of the rope and I was compelled to rope him again This time he would not keep his head high enough out of the water to enable me to get the rope over him so we were compelled to run up close and hang the noose on the end of the boat hook By dropping the noose over his head and carefull allowing it to stay slack until he had gotten one or both legs through we at last succeeded in getting him fast once more and started to the ship but not however before he had made one or two unsuccessful attempts to climb into the launch The placing of the noose over his head with the boat hook had its



STRUGGLE OF THE BEAR IN RESISTING TOWING

FINALLY THE ROPE HELD

THE BEAR REPEATEDLY THREW OFF THE LASSO

Photographs copyright 1910 by Paul J Rainey

were something terrific, and in a moment he had thrown the rope off his neck and was free. Recoiling our rope, we threw it and caught him again, and again he fought his way out of the noose to freedom This was repeated many times. He rarely stayed in the rope for more than three or four minutes at a time, as the noose would slip over his small head very easily, when we would be compelled to go back and start all over again.

Finally, however, the rope held, and we succeeded in getting the bear to the ship, when our men swung out the large crane or derrick, operated by a powerful steam winch, to hoist him aboard. When we passed the rope to landed very neatly on the seat of the other side

The bear seemed to have an idea of getting into the launch, and we had to punch him away with the boat hook Finally we succeeded in roping him and this time I took good care to leave the rope slack until he had put his forelegs through it, when I took a turn with our end of the rope around a cleat just as the bear was busy climbing out on the ice. In the excitement, we had neglected to reverse the engine, and when he went out on the ice he very nearly took the launch with him To have a 900 or 1,000-pound bear fastened to your launch and dragging you out on the ice, under a full head of steam, disadvantages, and was rather dangerous, because we were compelled to go very close to the bear

We towed him to the ship swung out the crane, fastened the hook onto the rope and in the twinkling of an eye Mr Green the mate had hoisted him high into the air and swung him over the ship's deck This caused a wild stampede among the Eskimos who were perfectly familiar with the strength and power of a full grown male polar bear Willing hands were at the swinging tackle of the derrick, however and in another moment we had the roaring, raging monster over the hatch of number one hold. As soon as he had been gently low

ered, all hands made a wild rush for the hatch to have a look at our pet

We found him surprisingly cool, merely sitting on his haunches growling and making the champing noise peculiar to bears when angry The rope was still around him but no weight being on it the noose was quite loose and as soon as he moved around it fell off

The next day to my surprise our captive ate small pieces of bread and meat that were thrown down to him Then the question arose how shall we get him into the cage? We needed some of the coal under the bear to keep the ship trimmed *It was a very serious situation* as the firemen did not show any willingness to go down for the coal At once we set to work to knock our small cages to pieces and build a larger one some ten feet long and six feet broad and high We used the iron bars for the door and the sheet iron for the bottom

After starving our bear for four or five days, we pieces of bread and meat that were thrown down to him fresh water inside the cage and lowered it down to the bear He started directly in but the sailor who was working the trap door let it drop too soon and the bear held it up with his back while he backed out

This episode seemed to make the bear very angry for he jumped up on the top of the cage and found that he could put his head and forepaws over the edge of the hatch and onto the deck!

Again there was a wild stampede of Eskimos sailors and dogs for it looked as if he surely would be up on the deck in an instant In the excitement Michael, the wheelman left the wheel and for a moment everything was in a state bordering on panic

At this point one of the sailors did a very brave thing He ran up and struck the bear heavily over the head with a deck mop whereupon after giving a savage growl the animal went back into the hold It was fortunate that he did so for had he gone overboard in the heavy sea that was running it would have been impossible to have stopped and picked him up, and we would have been compelled to shoot him.

Immediately we hoisted the cage out, and waited another twenty four hours, when it was again lowered with a good supply of walrus meat and fresh water, as before. This was quite enough for "Silver King" (as we named him) and in he went Without taking time to untie the rope that held the trap-door, we cut it; the door fell into place, and our bear was in his cage Again the steam winch was brought into play, and we soon had both cage and bear hoisted on deck

As the crowd of Eskimos and sailors collected around in front of the cage, the bear made terrible lunges at them and every time he lunged at the bars it was impossible for the Eskimos to stand still They simply had to break and run

Everything went well until we struck warm weather, and started washing him off with the deck hose every morning Although he had quieted down, this morning ablution business did not suit him at all, and then it was that he made up his mind to get out The construction of the cage was much too light, and on a dozen different occasions he very nearly succeeded in escaping It was terrifying to see him grab hold of the smooth side of the cage with his teeth and tear out splinters a foot long This we finally overcame by nailing a board over *each hole with large spikes through it*; but "Silver King" was very clever about biting around those spikes and never to my knowledge did he scratch himself

One night during a terrible storm the cage broke loose and as the water was running free of the decks, it looked as if he was surely going overboard The alarm was sounded and the entire crew turned out to help secure the cage After heaving the ship to and slowing her down a bit, they succeeded in getting on the well-deck and making the cage fast Another time while we were at supper a sailor put his head in at the door and with a respectful salute said "Sir the *bear is out!*" *Someone said, very sensibly*, "*Please clo*[se] the door!"

It seemed rather dangerous to go down on the well deck, as it was a very dark night. However, we got some lanterns, and hurrying down to the cage we found that the bear really had his head and shoulders out. With the aid of a stout boat-hook, we succeeded, however, in driving him back in, and soon had the hole boarded up After this we always kept a sailor watching the bear, day and night; and I believe we must have driven several thousand nails into the sides of that cage After our arrival at City Island I always kept my big 401 Winchester handy in case of an emergency

After Dr Hornaday and his men unloaded the bear at City Island an amusing incident happened The police captain of the precinct through which they were going to take the bear, got very much worried for fear he would get out, especially after I explained to him that the 32 calibre revolvers his officers were carrying would only serve to get him well stirred up He asked me if I would loan him a real gun which I was very willing to do, and after he had called in one of his officers, I gave him a long discourse on how to load and fire a 401 Winchester A half hour afterwards, seeing the officer parading up and down the dock with the 401, much to the admiration of several hundred men and boys, I decided to see if he still remembered his instructions I said to him: "Supposing the bear got out, and you wanted to shoot him, how would you go about it?" Pointing to the safety catch on the side, he said: "I would push the jigger over and pull the trigger" As I had purposely not placed any cartridges in the barrel he could not have done any great execution

I ask indulgence of my readers for this somewhat lengthy article on catching my bear I am not an author, and probably never will be one, so I hope they will look upon my article with the greatest indulgence—Reprinted from the New York Zoological Society's Bulletin

The Physics of the Polar Seas

Scientific Aspects of the World's Icy Regions

Almost all our knowledge of the physics of the Arctic Ocean is derived from the observations made by Nansen during the drift of the Fram although something has been contributed by the more recent explorations of Amundsen (1901) and the Duc d'Orleans (1905)

The Arctic basin is the northernmost of the deep depressions which lie north of the Atlantic and are separated from it and each other by submerged mountain chains The first of these ridges extends from Scotland through the Faroe Islands and Iceland to Greenland Its crest is nowhere more than 2 000 feet below the surface The most northerly ridge stretching from Greenland to Spitzbergen has not been completely explored but it is not believed to be more than 2 600 feet below the surface at any point As the sea between Spitzbergen and Norway and Bering Strait is shallow the polar basin has no deep connection with the great oceanic basins It forms what is called a Mediterranean basin i e an isolated deep sea in which the temperature and salinity from surface to bottom differ from those of the open ocean at corresponding depths The deep Arctic basin extends from the Greenland Spitzbergen ridge to and beyond the islands of New Siberia but its eastern limit is not exactly known The shallow sea which covers the submerged part of Siberia is from 310 to 370 miles wide and is rarely more than 330 feet deep New Siberia Franz Josef's Land and other islands rise from this submerged continental slope north of which the sea bottom descends rapidly to the great depths of 10 000 to 12 500 feet recorded by Nansen

At the bottom of the Arctic basin the water is warmer and saltier than that of the adjacent seas of Greenland and Norway The waters of the basin are divided into three strata: A cold and not very salt stratum about 650 feet deep a warm salt stratum extending from the depth of 650 feet to that of 2 600 feet and a cold salt stratum extending from the depth of 2 600 feet to the bottom

This phenomenon is due to a discontinuity in density between the superficial layer which is diluted with river water and the bottom layer so that the warmer water of intermediate density flows in between them from the south Nansen's observations all of which were made at the same place and within a short time show minimum temperatures at depths between 160 and 200 feet and maxima between 1 000 and 1 300 feet below which point the temperature decreases slowly to a second minimum near the bottom The proportion of salt increases rapidly from the surface to a depth of between 650 and 820 feet where it is about 3 51 per cent and then remains nearly constant to the bottom

In the superficial cold stratum the temperature varies from 32 deg to 28 8 deg F while the salinity increases from 3 per cent near the surface to 3 47 per cent at the depth of 650 feet This stratum is composed of fresh water derived chiefly from Siberian rivers mixed with sea water coming from the south The precipitation in the Arctic itself is comparatively insignificant Hence the polar sea presents very favorable conditions for the formation of ice which increases the salinity and density of the water immediately beneath the ice and this sets up a rather active vertical circulation within the limits of the cold superficial stratum especially near the coast The hummocks formed by ice drifting together often rise 20 feet above the water surface, which corresponds to a submerged depth of 160 feet, unless they are broader below than above Some solitary blocks are certainly deeper than this The water in contact with the ice is cooled to the freezing point corresponding to its salinity These conditions indicate a minimum temperature of 28 6 deg F at a depth of 200 feet which is approximately the case The calculated and observed temperatures agree exactly however only to a depth of about 66 feet As the depth increases beyond 200 feet the temperature rapidly increases to 32 deg F at a depth of 590 to 660 feet The isothermal surface of 32 deg F is the boundary between the superficial cold stratum and the intermediate warm stratum

Annual variations in temperature and salinity are caused by freezing and thawing In open channels between the ice floes in summer Nansen observed a stratum sometimes 10 feet deep of nearly fresh water having a temperature of 32 deg F or higher distinctly separated from the colder and saltier water beneath Often this surface of separation was marked by fringes and long horizontal needles of ice or even by a continuous sheet of ice in narrow channels This layer of fresh water disappears in autumn

As the ice drifts across the polar basin it increases in thickness each year because much more ice is formed in winter than is melted in summer As the "Fram" drifted westward, the salinity of the surface water increased and its temperature (equal to the freezing point corresponding to the salinity) diminished

The superficial cold stratum is deepest toward the east as it is derived chiefly from Siberian rivers Nansen found its depth 660 feet north of New Siberia but only 560 feet in its eastern part

The intermediate warm and salt stratum is characterized by a temperature above 32 deg F and a salinity exceeding 3 47 per cent It is evidently derived from the deeper portions of the Gulf Stream which, deflected by the subaqueous plateau between Spitsbergen and Norway skirt this plateau and the east coast of Spitzbergen near which they rise over the Greenland Spitsbergen ridge, and flow into the Arctic basin Here they are turned to the east by the earth's rotation and flow along the edge of the submerged base of Siberia

As the Gulf Stream water is confined between two cold strata it becomes colder as it advances eastward It shows a maximum temperature of 33 8 deg F at a depth of 1 050 feet, and a maximum of 32 6 deg F at a depth of 1 475 feet, north of New Siberia At the same time the thickness of the stratum warmer than 32 deg F gradually diminishes The lower isothermal surface of 32 deg F is found at depths of 2 950 feet at Spitsbergen and 2 625 feet near New Siberia

The cold stratum below shows a uniform salinity of 3 51 per cent, while its temperature diminishes from the lower isothermal of 32 deg F to a minimum of 30 6 deg F near the bottom A small increase below this point is due in Nansen's opinion to the internal heat of the earth At a depth greater than 3,300 feet the temperature increases eastwardly, in which direction the temperature of the intermediate warm stratum diminishes Hence Nansen conjectured that these two strata were composed of the same Gulf Stream water which had become cooled during a descending spiral course round the pole But as this water is protected from radiation by the Arctic water above, and contact with the latter cannot cool it to the observed bottom temperature Amundsen's observations in Barents Sea suggest a better explanation The superficial waters of the Gulf Stream enter this sea where by cooling and forming ice in winter along its shores, they yield the cold and very salt bottom water of the central depression There is no deep channel by which this cold water can enter the Arctic basin but the same action probably takes place north of Nova Zembla and Franz Josef's Land and whence the cold water can flow into the polar basin

This description of the three strata of the Arctic ocean is condensed from an article in *La Nature* by Th Hesselberg who gives the information summarised below

The distribution of density can be deduced from the observed distribution of temperature and salinity In the Eastern Hemisphere the surfaces of uniform density slope downward toward the east, most steeply near the surface but very distinctly throughout the upper cold stratum, producing an eastward current at the bottom of this stratum and a westward current at the surface In general the forces due to differences of density conspire with the action of the prevailing winds on the rough ice to produce a current flowing over and on both sides of the pole from Bering Strait to the passage between Greenland and Europe, through which the waters of both the Siberian and the Canadian rivers escape from the Arctic basin The ice closely follows these lines and consequently appears to drift eastwardly in the Western and westwardly in the Eastern Hemisphere but the water immediately beneath the ice, more strongly influenced by the earth's rotation exhibits a tendency toward a circulation from west to east around the pole

The drift of the ice across the polar basin usually occupies three or four years Hence the appearance of the ice varies greatly with the locality It is thin and smooth near the Siberian coast but becomes thick and rough as it approaches Greenland The ice is continually subjected to lateral pressure due to winds and currents, which produces undulations and ridges It is very much distorted along the north coast of Greenland against which it is forced by the current The expansion of ice in cooling produces enormous pressure in severe winters, and piles the ice into great hummocks These, however, are small in comparison with the icebergs, detached from the land ice of Greenland, which drift southward with the polar current. Some icebergs rise more than 300 feet above the water surface, and probably extend to depths of 1,300 to 1,600 feet They are less compact than sea ice, as they consist entirely of compressed snow Icebergs have been encountered in latitudes less than 40 degrees near the American coast, but they are rarely seen south of the Faroe Islands off the cast of Norway

Although the Antarctic region, occupied by a large continent surrounded by water presents conditions precisely opposite to those of the Arctic basin, the two polar seas have some phenomena in common The Antarctic is still very imperfectly known

The melting of the great masses of ice detached from the Antarctic continent produces a superficial cold stratum of small salinity in the southern parts of the great oceans. The "Gauss" encountered, at 65.5 deg. S lat., a stratum 2,460 feet deep, having temperatures below 32 deg F and salinities increasing from 3.30 per cent at the surface to 3.46 per cent at its base. A minimum temperature of 28.6 deg. F was observed at

a depth of 300 feet. This is three times the depth of the Arctic minimum. The difference is due to the vast mass of the Antarctic icebergs in comparison with the Arctic hummocks

Below this cold stratum to a depth of about 6,500 feet, extends a stratum of water warmer than 38 deg F having a uniform salinity of 3 46 per cent. The same salinity is found at still greater depths, but the tem perature gradually diminishes to 31 3 deg F

We find here, then, a warm stratum between two cold strata, as in the Arctic The upper cold stratum is evidently moving northward, while the warmer but denser intermediate stratum consists of water flowing southward from warmer regions The force deduced from the distribution of salinity and density at the sur face is directed northward but the prevailing winds aided by the effect of the earth s rotation deflect the surface current toward the west This current is finally merged in the eastward current which marks the limit of the Antarctic circulation, at about 50 deg S lat The density of the surface water diminishes in going either northward or southward from this line

The Antarctic ice is partly marine and partly terres trial Some of the colossal icebergs are composed chiefly of blue ice formed along the shore Antarctic icebergs are seldom encountered north of latitude 45, but in 1894 the remnants of one were seen in 26½ deg S lat

Our knowledge of the polar seas will almost certainly be improved in a few years A ship drifting with the ice is in the best possible condition for observing the physics of the sea The expedition headed by Roald Amundsen will start from Bering Strait in the autumn of 1911 equipped with the most improved oceanographic apparatus The plan is to cross the Arctic basin as near the pole as possible Antarctic expeditions are also projected

Characteristic Features of Rocky Deserts

Relation of Protective Crust to Ravine Formation

By Dr H Burmester
